# Insights into the sodiation mechanism of hard carbon-like materials from electrochemical impedance spectroscopy†

Konstantin Schutjajew, <sup>‡\*a</sup> Tim Tichter, <sup>b</sup> Jonathan Schneider,<sup>b</sup> Markus Antonietti, <sup>a</sup> Christina Roth <sup>c</sup> and Martin Oschatz <sup>‡\*a</sup>

To render the sodium ion battery (SIB) competitive among other technologies, the processes behind sodium storage in hard carbon anodes must be understood. For this purpose, electrochemical impedance spectroscopy (EIS) is usually undervalued, since fitting the spectra with equivalent circuit models requires an *a priori* knowledge about the system at hand. The analysis of the distribution of relaxation times (DRT) is an alternative, which refrains from fitting arbitrarily nested equivalent circuits. In this paper, the sodiation and desodiation of a hard carbon anode is studied by EIS at different states of charge (SOC). By reconstructing the DRT function, highly resolved information on the number and relative contribution of individual electrochemical processes is derived. During the sloping part of the sodiation curve, mass transport is found to be the most dominant source of resistance but rapidly diminishes when the plateau phase is reached. An equivalent circuit model qualitatively reproducing the experimental data of the sloping region was built upon the DRT results, which is particularly useful for future EIS studies on hard carbon SIB anodes. More importantly, this work contributes to establish EIS as a practical tool to directly study electrode processes without the bias of a previously assumed model.

## Introduction

Lithium-ion batteries (LIBs) are indispensable for the small-scale storage of electrical energy, *e.g.* in portable electronic devices or electromotive applications. However, due to the scarcity and the uneven geographical distribution of many key components required in LIBs (*e.g.* cobalt ores and lithium salts) alternative solutions based on more abundant materials moved into the focus of current research. Among them, the sodium ion battery (SIB) is probably the most attractive system, as it offers an operational voltage and an energy density similar to LIBs. Furthermore, it shares many aspects of cell chemistry with its lithium-analogue. The similarity between lithium and sodium provides the opportunity that many components such

as the electrolyte and the range of cathode materials can be almost directly adopted from LIBs to SIBs.<sup>1,2</sup>

Yet, in contrast to LIBs, an anode material with high sodium storage capacity at a potential close to Na/Na<sup>+</sup> and at the same time with a high operational safety, is much more complicated to find. While the implementation of metal oxides and alloys in conversion anodes promises high theoretical capacities, this approach is impaired by the significant volume expansion during operation, causing severe limitations. Hence, such materials are still mainly relevant from an academic point of view.<sup>3</sup>

In case of LIB, the most widely used anode material is graphite. Graphite can form a series of binary Li-C intercalation compounds during the lithiation process which contributes to an excellent capacity which is theoretically limited to 372 mA h g<sup>-1</sup> for the final stoichiometry of LiC<sub>6</sub>. Unfortunately, graphite does not show any considerable sodium storage capacity as no binary intercalation compounds of graphite and sodium are known.<sup>4</sup> Contrarily, the use of carbonaceous materials as anode is a practically promising approach owing to the considerable alkali metal storage capability of most carbon types and a virtually unlimited amount of possible carbon structures and modifications.<sup>5</sup>

Particularly the so-called hard carbons (HCs) are considered as an alternative to graphite and have been subject of extensive research activities for many years.<sup>3,6</sup> Hard carbons are carbon materials without a long-range order, usually considered non-graphitizable.

They can be best described as turbostratically contorted, curved graphene layers that are—to some extent—aligned in parallel to each other, forming a material with partially graphitic domains as well as small internal cavities.<sup>7,8</sup>

Hard carbons are usually obtained from precursors, which develop a high degree of cross-linking during pyrolysis. However, their particular structure is not only dependent on the type of precursor but can also be significantly influenced by the synthesis conditions.<sup>9</sup> Hence, structural features like porosity, carbon binding motifs, or even heteroatom content must be considered when employing a hard carbon for sodium storage. All of these properties influence the sodium storage mechanism and thus the operating potential of the anode at the respective state of charge, represented by the voltage profile.<sup>7</sup> Profound understanding of their individual and combined influence on sodium storage is a crucial requirement for future targeted improvement of the capacity and stability of HC anodes.

The voltage profile during the sodiation of hard carbons can be generally divided into three regions: (1) a sloping region at potentials higher than 1.5 V *vs.* Na/Na<sup>+</sup> extending over a low capacity range, (2) a sloping region with a slower potential decay at approx. 1.5–0.2 V *vs.* Na/Na<sup>+</sup>, and (3) a voltage plateau at 0.2–0.0 V *vs.* Na/Na<sup>+</sup>.

While it is agreed upon that ion adsorption to defect sites is responsible for the first, high potential stage, the assignment of distinct chemical processes corresponding to the latter two stages is still under debate.<sup>10–13</sup> Multiple characterization tools have been applied in combination with suitable model materials to elucidate the corresponding mechanisms.

Stevens and Dahn were the first who studied the sodium insertion into hard carbon electrodes, using *in situ* X-ray scattering techniques. They reported an extension of the (002) interlayer spacing during the sloping and a change in electron density in the ultramicropores during the plateau phase.<sup>6,14,15</sup> Therefore, they assigned the intercalation of sodium between the graphene layers to the sloping, and the pore filling to the plateau regions, respectively. Their results were corroborated by X-ray diffraction and NMR-data of other groups.<sup>16–18</sup> Liu *et al.*<sup>19</sup> suggested that intercalation between graphene layers with larger interlayer spacing contributes to the charge storage in the plateau as well. This was confirmed later on by Ji *et al.*<sup>20</sup> employing the galvanostatic intermittent titration technique (GITT). More recently, Bai *et al.* selectively adjusted the defect- and micropore-content of a HC-material, and found out that the former is closely related to the sloping and the latter to the plateau region.<sup>21</sup> In a series of small-angle and wide-angle X-ray scattering (SAXS and WAXS) experiments, Morikawa *et al.*<sup>22</sup> observed the appearance of characteristic scattering peaks related to quasimetallic sodium confined in narrow micropores only at later stages of the plateau region, very close to 0 V *vs.* Na/Na<sup>+</sup>. Those findings indicate not a single phenomenon, but a fluent passage from intercalation processes into graphene interlayers to micropore deposition of sodium to be responsible for the voltage plateau. While we agree with the common view on the role of micropores in sodium storage, we consider the explanation of intercalation into the graphitic interlayer space during the sloping phase as

somewhat incomplete. This is justified by the typically linear decrease in potential which hints towards an adsorptive mechanism occurring, where sodium is present as a cation and the electron remains mostly at the electrode.<sup>23,24</sup> Alternatively, a phase similar to a solid-solution could be imagined at this stage of sodiation.<sup>25</sup> NMR studies generally support this view, since the chemical shift of elemental sodium remains similar to that of positively charged sodium ions during the sloping region and, on the other hand, the well-studied process of intercalating lithium into graphite results in a strong and distinct chemical shift, which is not the case during the sloping region in a sodium anode.<sup>17,18,26,27</sup>

So far, the common view on the sodiation mechanism of HCs is mainly based on the results of charge/discharge and cyclic voltammetry measurements combined with (*ex situ*) structural analysis.<sup>9,20,28,29</sup> Another characterization tool that is widely applied for the investigation of practically all kinds of electrochemical processes is electrochemical impedance spectroscopy (EIS).<sup>30</sup> Though, more detailed insights into the sodiation process of hard carbons might be gained from EIS, the possibilities of this method have not been exploited to their full extent yet. This is potentially caused by the fact that the most commonly applied method for EIS-analysis—equivalent circuit fitting (ECF)—requires for a relatively precise knowledge of all the possible mechanistic aspects of the system under study. Since due to the multiplicity of processes involved such an information is a mere guess for HC based sodium-ion anodes, ECF might provide rather ambiguous results instead of physicochemically relevant parameters.

In order to overcome these drawbacks, the EIS-spectra can be evaluated alternatively in terms of the distribution of relaxation times (DRT) analysis. This approach does not require any *a priori* knowledge on the system under investigation. In contrast, it offers direct information on the number of individual processes occurring during the reaction as well as their relative contribution to the total impedance. Furthermore, it provides a significantly enhanced resolution, when compared to the Nyquist or Bode representation of EIS data which can unravel up to three processes per frequency decade. This method has already been successfully applied successfully to solid oxide fuel cells and was proven viable for a LiFePO<sub>4</sub> cathode<sup>31</sup> as well as for lithium ion full cells.<sup>32</sup> Porous carbon anodes in LIBs as well as metallic sodium anodes were investigated by DRT, recently.<sup>33,34</sup> However, to the best of our knowledge a DRT-study of a hard carbon sodium ion battery anode has not been performed yet.<sup>31,32,35–37</sup>

Therefore, the scope of the present work is to apply the DRT-method for the investigation of the Na storage in sodium-ion anodes on a fundamental level and to gain primary insights on the sodiation mechanism. For this purpose, impedance spectra of a hard carbon-like anode material are recorded at a broad range of different states of sodiation/desodiation and subsequently analyzed with the DRT approach. Following the method of Schmidt *et al.*,<sup>31</sup> data from symmetrical cell measurements is compared to hard carbon/sodium half-cell experiments and the processes are assigned to the respective cell components and processes. Most importantly, the nature of the sodium species formed during the low-voltage plateau phase of the sodiation is elucidated and the kinetics of their formation is found to be

strikingly similar to that of sodium plated in the bulk of the electrode. This finding supports previous models of quasi-metallic phases forming in carbon nanopores and provides profound insights about alkali-ion storage in hard carbon-like materials.

## Results and discussion

### Data processing

Experimental data of electrochemical impedance spectroscopy is usually evaluated by exploiting equivalent circuit models from which the electrokinetic parameters are obtained by complex non-linear least-square (CNLS) fitting routines. However, in many electrochemical systems, especially in electrodes made of complex materials with a rough or porous structure, equivalent circuit models, constructed from the three basic circuit elements resistor R, capacitor C and inductor L, are inherently ambiguous in describing the measured impedance spectra. This is caused by the fact that real systems are mostly characterized by parameters with a certain distribution.<sup>30,38</sup> In such cases distributed elements, like the constant phase element (CPE), provide a mathematically better fit but are not necessarily more realistic in describing an electrochemical system.

Another way of approximating the measured EIS data is the analysis of their distribution of relaxation times (DRT). By considering a continuous series connection of RC-elements (time constants) any electrochemical system might be expressed by the following (DRT) integral equation:

$$\frac{Z(\omega) - Z_\infty}{Z_0 - Z_\infty} = \int_0^\infty \frac{g(\tau)}{1 + j\omega\tau} d\tau = \int_{-\infty}^\infty \frac{\tau g(\tau)}{1 + j\omega\tau} d\ln(\tau) \quad (1)$$

In eqn (1),  $Z(\omega)$  represents the measured impedance and  $\omega$  the angular frequency with  $\omega = 2\pi f$ .  $Z_\infty$  and  $Z_0$  are the impedance for the two limiting cases with  $f$  approaching infinity or zero, respectively.  $j = \sqrt{-1}$  the imaginary unit,  $\tau$  is the time constant with  $\tau = 2\pi\omega^{-1} = RC$  and  $g(\tau)$  stands for the normalized distribution of relaxation times function which has to be determined. Obtaining the function,  $g(\tau)$ , according to eqn (1) requires for solving a Fredholm integral equation of the first kind.<sup>30</sup> This is a mathematically ill-posed problem in the definition of Hadamard. In case of experimental, *i.e.* non-ideal data, this enforces that the solution (if it exists) might not be unique and/or suffer from strong oscillations. Therefore, a variety of approaches for approximating  $g(\tau)$  employ regularization methods to stabilize the solution. Among them, *e.g.* Fourier transformation,<sup>35,39</sup> Tikhonov regularization,<sup>37,40–43</sup> maximum entropy,<sup>44,45</sup> or evolutionary programming<sup>46,47</sup> have been proposed. At this stage, it is exceptionally worth to note that choosing a suitable regularization is crucial for obtaining a reliable DRT. Herein, we are using Tikhonov regularization to reconstruct the underlying DRT function from our experimental data. We chose this approach owing to its ease of implementation and its capability to faithfully reproduce a DRT even in rather complex cases.<sup>48,49</sup> Our methodology is similar to the one outlined by Hahn *et al.*<sup>37</sup> and can be briefly summarized as follows.

Since the DRT is computed numerically, eqn (1) is first discretized.

$$\frac{Z(\omega) - Z_\infty}{Z_0 - Z_\infty} = \sum_{k=1}^n \frac{\gamma(\tau_k)}{1 + j\omega\tau_k} \quad (2)$$

Secondly, it is re-formulated using matrix notation.

$$\mathbf{z} = \mathbf{K}\boldsymbol{\gamma}. \quad (3)$$

In eqn (2),  $\gamma(\tau) = \tau g(\tau)\Delta\ln(\tau)$  where  $\Delta\ln(\tau)$  is the spacing of  $\tau$ -increments spanning a logarithmic grid. In eqn (3), the vector  $\mathbf{z}$  contains all  $m$  measured data points and  $\mathbf{K}$  is the  $m \times n$  kernel matrix, whose entries are given by eqn (4).

$$k_{m,n} = \frac{1}{1 + j\omega_m\tau_k} = \frac{1}{1 + j2\pi f_m\tau_k} \quad (4)$$

with:  $m = 1, 2, \dots, m$  and  $n = 1, 2, \dots, n$

The vector  $\boldsymbol{\gamma}$  contains the sought-after distribution function. The number of time constants  $n$  is chosen as an integer multiple of the number of measured data points.

$$n = a \times m; a = 1, 2, 3, \dots \quad (5)$$

For the calculations related to this paper we set  $a = 10$ , as a suitable balance between resolution of the obtained DRT and the time required for computation. The pre-defined time constants are chosen to span an equally spaced logarithmic grid between  $\tau_{\min}$  and  $\tau_{\max}$ , obtained as eqn (6), where floor and ceiling functions of  $x$  are denoted as  $\lfloor x \rfloor$  and  $\lceil x \rceil$ , respectively.

$$\tau_{\min} = 10 \left\lfloor \left( \log_{10} \left( \frac{1}{f_{\max}} \right) \right) - b \right\rfloor_s \quad (6)$$

$$\tau_{\max} = 10 \left\lceil \left( \log_{10} \left( \frac{1}{f_{\min}} \right) \right) - b \right\rceil_s; b = 0, 1, 2, \dots$$

Herein, parameter  $b$  allows for an expansion of the time domain beyond the range of experimental frequencies. This enhances the quality of the fit at the boundaries of the measured spectrum. By our experience it is sufficient to use  $b = 3$ .

Having set up the time constants and having constructed the kernel matrix  $\mathbf{K}$ , the DRT is obtained by solving eqn (3) with respect to  $\boldsymbol{\gamma}$ . This is achieved by least-squares minimization and finding:

$$\min\{\|\mathbf{K}\boldsymbol{\gamma} - \mathbf{z}^2\|\} \quad (7)$$

where  $\|\cdot\|$  denotes the euclidian norm. Since this is an ill-posed problem, we apply Tikhonov regularization by extending the cost function by a regularization term according to eqn (8).

$$\min\{\|\mathbf{K}\boldsymbol{\gamma} - \mathbf{z}\|^2 + \lambda\|\mathbf{M}\boldsymbol{\gamma}\|^2\} \quad (8)$$

Here,  $\lambda$  is the regularization parameter and  $\mathbf{M}$  the regularization matrix. In the native case, which was also used for the calculations presented herein,  $\mathbf{M} = \mathbf{I}$ , the  $n \times n$  identity matrix. Further options are discussed in ref. 37.

Since negative contributions to the impedance are not reasonable according to eqn (1), we used a non-negative least-squares (NNLS) solver.<sup>50</sup> This, however, causes three important implications.

Any possible inductive contribution to the impedance will be neglected during the fitting routine.

The NNLS solver cannot handle complex valued inputs and it is only able to deal with problems in the form of eqn (7), but not in the form of eqn (8).

Implication (I) will not be a problem, since our data does not show any sign of inductive contribution. Consequently, utilizing the somewhat restricted NNLS approach is well justified. Fortunately, implication (II) can be circumvented as follows. Implementing complex valued inputs is avoided if only the real or imaginary part of the impedance is considered. It might be defined that:

$$\min\{\|K^*\gamma - z^*\|^2\}$$

with  $K^* = \Re(K)$  and  $z^* = \Re(z)$   
 or  $K^* = \Im(K)$  and  $z^* = \Im(z)$  (9)

For linear and time-invariant data obeying the Kramers–Kronig relations<sup>51</sup> it may be justified to use either one of real or imaginary part for calculating the DRT. However, in the presence of noise, which is practically unavoidable in experimental data, it is always beneficial to invoke all available information. Thus, a combined fit taking into account real as well as imaginary part can be obtained by letting:

$$K^* = \begin{bmatrix} \Re(K) \\ \Im(K) \end{bmatrix} \quad (10)$$

and:

$$z^* = \begin{bmatrix} \Re(z) \\ \Im(z) \end{bmatrix} \quad (11)$$

Finally, the problem stated in eqn (8) is rearranged into a form similar to eqn (7) in order to be passed to the NNLS solver. This is achieved by using the expression in eqn (12).

$$\min\left\{\left\|\begin{bmatrix} K^* \\ \lambda I \end{bmatrix}\gamma - \begin{bmatrix} z^* \\ 0 \end{bmatrix}\right\|^2\right\} \quad (12)$$

Which is equivalent to eqn (13):<sup>52</sup>

$$\min\{\|K^*\gamma - z^*\|^2 + \lambda\|I\gamma\|^2\} \quad (13)$$

After having formulated the optimization problem in a way which fits into the NNLS solver (eqn (12)), the regularization parameter has to be defined. For the purpose of this work,  $\lambda = 0.1$  turned out to be a suitable balance between under- and overfitting.

### Structural and electrochemical characterization

The carbon material denoted as C-HAT-1600 used in this study is obtained from the direct thermal condensation of the nitrogen-rich precursor hexaazatriphenylene-hexacarbonitrile (HAT-CN). During the heat treatment the precursor molecules undergo condensation and cross-linking, resulting in a highly microporous, hard carbon-like network with significant nitrogen content, as was already reported by Walczak *et al.*<sup>53</sup> The fundamental structural and

electrochemical characterization of HAT-CN-derived materials was subject to previous work in our group and will therefore be treated only briefly in the following.<sup>54</sup>

The present sample of C-HAT-1600 is a hard carbon that is non-porous when analyzed by Ar physisorption at 87 K with a BET surface area of  $20 \text{ m}^2 \text{ g}^{-1}$  as shown in Fig. 1a. It contains 0.5 wt% of nitrogen according to elemental analysis. Despite the low surface area, a high irreversible capacity of  $379 \text{ mA h g}^{-1}$  can be seen in the first sodiation cycle in Fig. 1b and the material reaches a stable reversible capacity of  $216 \text{ mA h g}^{-1}$  in subsequent, capacity limited cycles. Despite the modest capacity values the material delivers, it is an interesting model substance to study the hard carbon sodiation mechanism for several reasons. It exhibits both sloping and plateau regions to reasonable extents and furthermore contains a sufficient amount of high-energy ion-adsorption sites due to the presence of heteroatoms. Therefore, sampling EIS-spectra along the sodiation curve of this material provides the opportunity to study the kinetics of each individual step of the sodiation process. Fig. 2a depicts the points in the sodiation curves at which EIS were recorded. Note that the elapsed time is plotted on the x-axis, in order to account for the relaxation steps, as the current pulse in each step only lasts

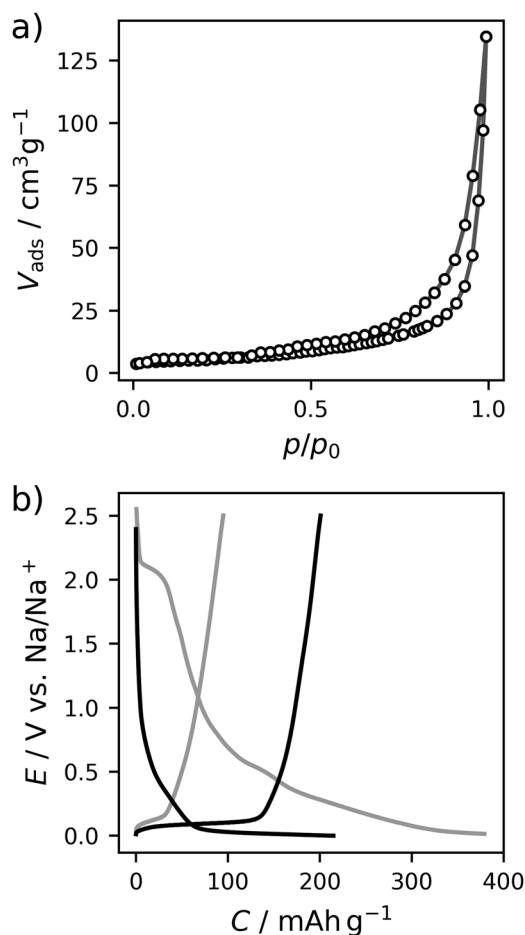

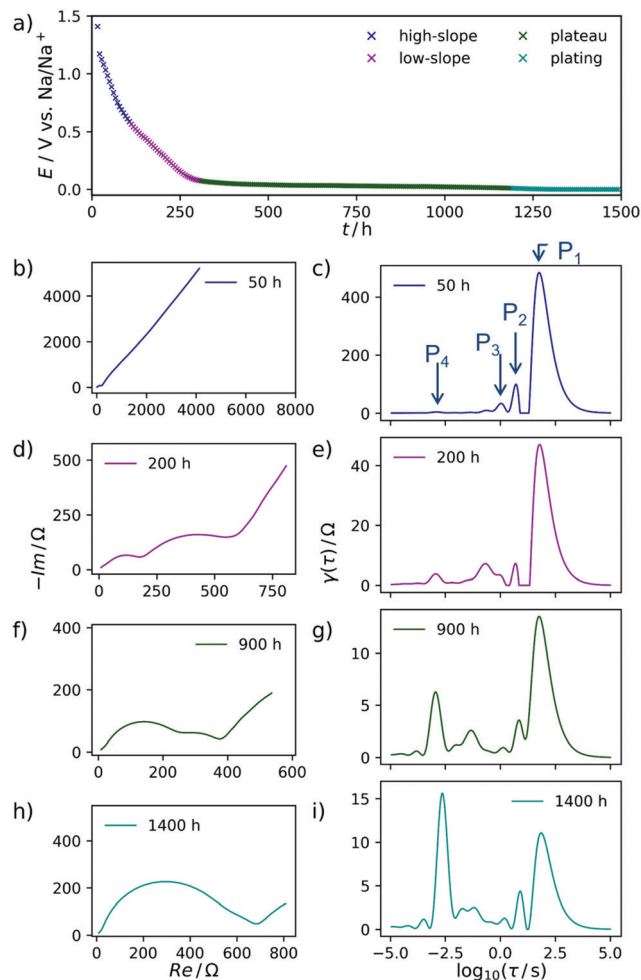

Fig. 1 (a) Ar physisorption isotherm at 87 K. (b) Galvanostatic charge-discharge curves recorded at  $18.6 \text{ mA h g}^{-1}$ . The first cycle (grey) and representative capacity-limited cycle (black) is depicted, respectively.

**Fig. 2** (a) Steady state sodiation curve of C-HAT-1600 showing the potentials at which EIS was recorded. Regions color-coded with respect to the nomenclature previously defined, (I) high slope, dark blue, (II) low slope, purple, (III) plateau, green, (IV) sodium plating, cyan. (b, d, f and h) Exemplary electrochemical impedance spectra at each defined sodiation stage. (c, e, g and i) DRTs corresponding to (b, d, f and h). The capacity axis is presented in a time dimension, as the chemical change observed occur on a time scale and can potentially not be overlapped in a rate description.

10 min. The curve shows four significantly distinct regions. These are (I) a sloping region with a higher slope (0–100 h, highlighted in blue), (II) a sloping region with a lower slope (100–300 h, highlighted in purple), (III) a prolonged plateau (300–1200 h, highlighted in green) and (IV), a region where the cell equilibrated around 0 V ( $t > 1200$  h, highlighted in cyan).

In Fig. 2b the respective Nyquist impedance is shown for each of the four aforementioned regions. All spectra, which have been acquired at equilibrium potentials above 0 V, share the same qualitative feature—one semicircle of around 200  $\Omega$  on the real axis in diameter.

A second arc, decreasing in diameter with an increasing degree of sodiation can be perceived after 50 h. It clearly manifests in the impedance data after 200 h.

The DRT of the cell at each of the SOC's is shown in Fig. 2c. Each peak corresponds to an RC-element with a characteristic

time constant  $\tau$  at the center of the peak. Therefore, it can be assigned to a certain electrochemical process which might (or might not) be coupled to mass transfer. The height of  $\gamma(\tau)$  can be interpreted as the impedance with which the respective process contributes to the total impedance of the cell at a given SOC.

### Interpretation of the EIS/DRT data

The ascending branch in the low-frequency region of the Nyquist-plots in Fig. 2 suggests the presence of a slow electrochemical process, *i.e.* diffusion, which plays an essential role in the sodiation of the hard carbons. This quantity will usually render a decent interpretation of the pure electrode kinetics exceptionally arduous. Schmidt *et al.*<sup>55</sup> approached a similar problem, yet related to LIB, by modelling the low-frequency part of the EIS of a LiFePO<sub>4</sub> cathode with a finite-length Warburg- in series with a capacitive element. By subtracting this portion from the experimental impedance data and finally performing DRT on the resulting spectrum, the authors were able to isolate the electrode kinetics. This procedure appears suitable for a system with relatively distinct and well understood processes underlying the EIS. However, the analysis of complex and less defined mechanisms—such as ones related to the sodium storage in hard carbons—should be kept as free from models and assumptions as possible. Therefore, we decided to use the raw impedance data for the calculation of the DRT in a first instance. Subsequently, we interpret the respective DRT results by assigning certain processes to the distinct signals of the DRT, and propose a mechanism which combines our own findings with insights known from the literature. Finally, we support our results by formulating a model which captures the experimentally observed trend.

As expected already from the evaluation of the Nyquist plots, the main contribution to the impedance during the first, steeper sloping region arises from a process with a slow time constant of approximately  $\tau = 19$  s, called  $P_1$  henceforth. Due to the large time constant and the non-closing shape of the Nyquist plot, this process is interpreted as diffusive mass transfer of an ion, presumably sodium ions reaching their binding sites in the SEI layer. Two additional processes,  $P_2$  and  $P_3$ , can be identified at  $\tau = 2$  s and  $\tau = 0.6$  s, respectively and one distinct and invariant peak  $P_4$  is found at  $\tau = 10^{-3}$  s. It stands to reason to assume that these are related again to diffusive Na<sup>+</sup> transport, here however already in the carbon material, after passing the SEI.

In the EIS, obtained during the less steep slope region, exemplarily shown at 200 h, the signals  $P_1$ ,  $P_2$ , and  $P_3$  are decreasing in height and area. Therefore, their contribution to the overall impedance (relative to the  $P_4$  peak) decreases, either. All spectra after 900 h are characterized by only two essential processes, one at  $\tau = 20$  s and one at  $\tau = 10^{-3}$  s, respectively. Due to the consistent nature of the process  $P_4$  within time and its relatively fast time constant, we propose that this particular process is related to electron transfer processes at metallic interfaces. After 1250 h the DRT-peak  $P_4$  is approximately doubled in height, which we explain by the formation of extended patches of metallic sodium starting to deposit on the working electrode from this

point in time. Once sodium plating has occurred, there should be no (or at most a negligible) difference between the working electrode kinetics and the sodium-metal counter electrode.

In a two-electrode setup the total impedance of both the working and counter electrode is measured. Therefore, to corroborate this assignment, the EIS of a symmetrical Na/Na cell was measured. The corresponding Nyquist plot and DRT are depicted in Fig. 3. Essentially, one semicircle is obtained in the Nyquist plot with a width being at least in the same range as the EIS of a charged Na/C cell after 900 h. The corresponding DRT shows the major peak at approximately  $\tau = 10^{-3}$  s. Meanwhile, an additional peak centered at  $\tau = 1$  s is obtained in the DRT of the hard carbon/sodium cell, which is related to the small tail on the imaginary axis at low frequencies in the Nyquist representation. This signal can be assigned to the diffusion of  $\text{Na}^+$  ions through the separator. The difference between the two DRTs therefore has to be related to the carbon/SEI system. This experiment additionally hints at the stability of the electrolyte as well as the formed SEI within the time scale relevant for this study. To obtain a decent understanding of the remaining two peaks of the sloping region, the evolution of the DRT over several SOCs has to be monitored. For this purpose, 3D waterfall plots are presented in Fig. 4, where the DRTs are plotted *versus* time.

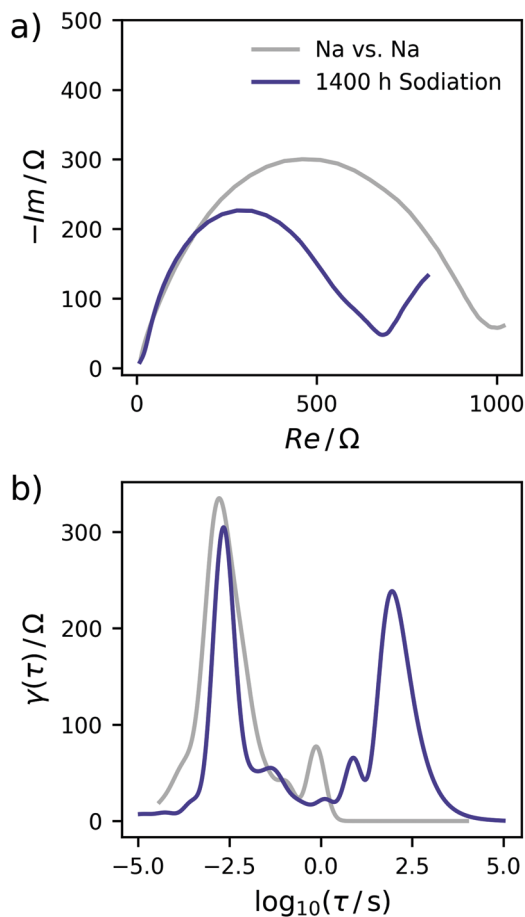

Fig. 3 (a) Nyquist plot of the symmetrical Na/Na cell. (b) DRT of the symmetrical cell. Data of the C-HAT-1600 anode is shown for comparison.

The specific characteristics of the DRTs over the course of sodiation are therein closely related to the potential/charge where it is taken. Therefore, the data were subdivided into the previously defined regions with (I) high slope, (II) lower slope, (III) plateau, and (IV) electroplating region. In the high-slope region the DRT is dominated by two strong and slow processes centered at  $\tau = 19$  s and 5 s. With further loading, these peaks are shrinking and shifting to slightly faster time constants ( $\tau = 16$  s and 2 s) towards the end of this loading stage.

Another important feature occurs throughout the second, low-slope phase in Fig. 4d which was formally attributed to the  $\text{Na}^+$  transport in the carbon phase. Besides further diminution of the  $\tau = 16$  s peak an additional splitting of the  $\tau = 2$  s peak into a signal which is constant and a process with a gradually decreasing relaxation time can be observed. This behaviour can be translated in a representative equivalent circuit model for the sodiation process, which is described and compared to the experimental results in the following section. The interplay between the processes  $P_1$  and  $P_2$  can be illustrated as follows: If  $P_1$  is due to the diffusion of Na-ions into the formed SEI and through it, it will stay relevant throughout the whole battery cycling process, where conductivity of this layer will of course improve with both increasing  $\text{Na}^+$  content and increasing driving potentials (for jump charge transport), thus explaining the slight shift and lowering relaxation strength with time. Exceeding a certain potential, the SEI ensured a steady sodium ion supply to the carbon, but  $P_1$  never disappears from the DRT, because the flux of sodium has to be ensured during the entire sodiation process. The carbon phase then can be loaded with increasing amounts of  $\text{Na}^+$  with increasing potential, as we also know from carbon supercapacitors. As  $P_2$  occurs mainly during the low-slope phase and becomes irrelevant as soon as  $P_3$  sets in, we assign it to the diffusive transport sodium ions into the carbon host to high adsorption energy binding sites. The faster process  $P_3$  is loading invariant and speculatively attributed to the faster electron transport in the defective carbon. The plateau phase sets in when the potential is close enough to the standard Na reduction potential so that  $\text{Na}(0)$  can be formed and deposited, *i.e.* the system moves from  $\text{Na}^+/\text{e}^-$  pair storage to sodium atom storage and deposition/intercalation. This region is split into an underpotential deposition region (where the materials environment adds stabilization energy which helps the sodium to be reduced), and an overpotential region where metallic sodium can form even without extra energy contributions. During the plateau phase between 300 h and 1150 h in Fig. 4e, the DRT does not change substantially as soon as the  $P_3$  mode is established. This indicates not only a kinetically homogenous process occurring in this voltage range, but also suggests that  $P_3$  is closely related to the sodium reduction, that is potentially the electron transfer through the carbon to reduce the preadsorbed sodium ions. This is in agreement with the common view on the sodiation of hard carbon anodes. Towards the transition of the plateau region into sodium electroplating a diminishing of the previously emerged DRT-peak at  $\tau = 10^{-1}$  s in favor of the  $P_4$ -peak can be observed, implying the end of carbon controlled processes and “free” overpotential electroplating.

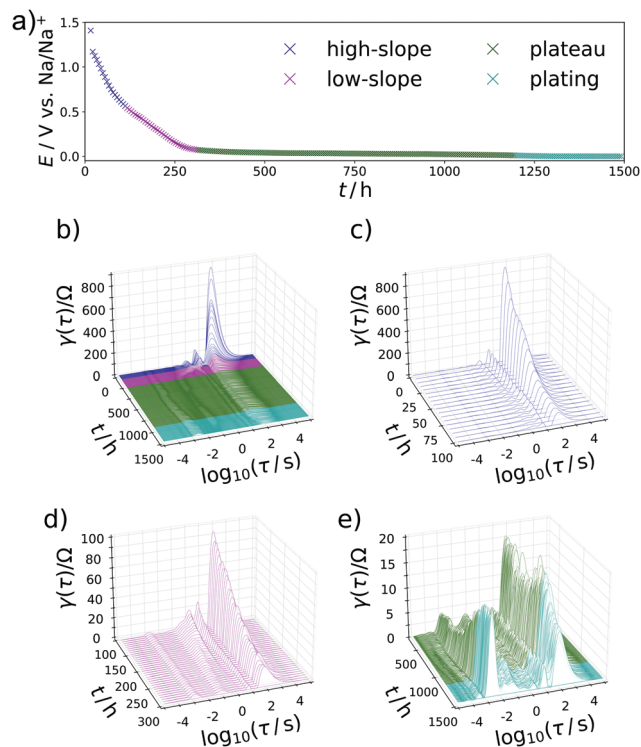

Fig. 4 (a) Steady state sodiation curve of the anode. (b) Waterfall plot of the DRTs calculated from each impedance spectrum against sodiation time. (c–e) Magnified view on the (c) high-slope, (d) low-slope, and (e) plateau and electroplating regions. The capacity axis is presented in a time dimension, in order to account for the relaxation phases.

### The desodiation process

This established procedure is now also applied to the desodiation process. However, when we compare equilibrium sodiation and desodiation curves in Fig. 2a and 5a, the desodiation plateau is much shorter in time than the sodiation plateau, at constant current. This leaking of energy is related to the chosen special experimental conditions. Unlike usually directly recorded charge-discharge curves, the presented recording of dielectric spectra in every point under load takes several weeks (1000 hours correspond to about 42 days). We found that the sodium structures formed in the sodiation plateau cannot be maintained in our experimental cell over such a prolonged time. This is mostly self-discharge, but on top the fact that metallic sodium species with a formal oxidation state close to zero in nanodimensions rearrange over time (*e.g.*, by coalescence or Ostwald ripening), leading to the formation of metallic sodium species not contacted by the anode. For this process to occur sodium must be neutral, as otherwise a rearrangement would not be possible.

The sloping region however is unchanged and extends over 200 h in both forward and reverse process. The impedance spectra and DRTs for the release of sodium (shown in Fig. 5b–f) are similar to the ones measured during respective stages of the sodiation process. It follows that processes occurring during the voltage slope are highly reversible in nature. This is of special relevance for the sloping region, where ion adsorption or the formation of a solid solution of  $\text{Na}^+$  in a negatively charged

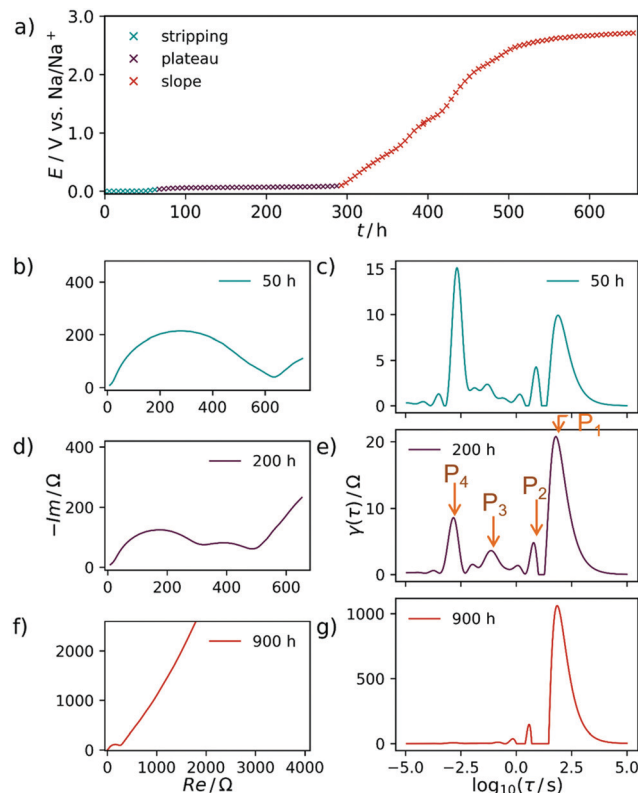

Fig. 5 (a) Steady state desodiation curve of C-HAT-1600 showing the potentials at which EIS was recorded. Regions color-coded as follows, (I) sodium electrostripping, cyan, (II) plateau, dark purple, (III) slope, orange. (b, d and f) Exemplary electrochemical impedance spectra at each defined sodiation stage. (c, e and g) DRTs corresponding to (b, d and f). The capacity axis is presented in a time dimension, in order to account for the relaxation steps.

carbon host is now plausible.<sup>25</sup> Any intercalation process in between of two graphitic layers would change the structure and cause an expansion of the material, which of course would cause a hysteresis of the charge and discharge curve but could not proceed in such a reversible manner.

The development of the impedance spectra and DRTs during desodiation is presented as waterfall plots in Fig. 6. Upon changing from the electrostripping region at 0 V to the plateau region, the DRTs are comprised of the same four signals as in the sodiation. As soon as the sloping mechanism begins after about 300 h, the high-frequency peak at  $\tau = 10^{-3}$  s again reduces, and low-frequency peaks begin to dominate the DRT, where the one at  $\tau = 2$  s develops first and reaches a steady state. After that, the signal at  $\tau = 16$  s gradually increases in significance. Remarkably, a shift in frequency of the peaks with SOC is not observed during the desodiation.

These data again show that diffusion of Na-ions is the main rate determining factor during the sodiation and desodiation of a hard carbon anode and by far outweighs processes such as charge transfer from support to carbon and from carbon to electrolyte. Improvement of the anode's performance can be achieved by adjusting its characteristics relevant for mass transport, such as particle size, porosity, and density, but the rate limiting step is related to the structure of the SEI, which is formed in the present case by an essentially uncontrolled

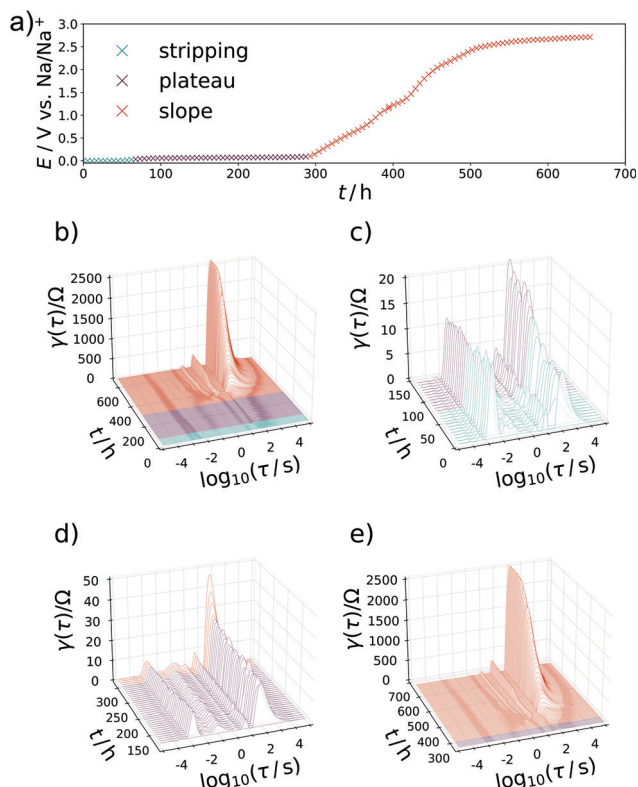

Fig. 6 (a) Steady state desodiation curve of the anode. (b) Waterfall plot of the DRTs calculated from each impedance spectrum against desodiation time. (c–e) Magnified view on the (c) transition from electrostripping to plateau, (d) transition from plateau to slope, and (e) development of the sloping region. The capacity axis is presented in a time dimension, in order to account for the relaxation steps.

random process in the first loading cycle. Further, the analysis of the cell by combined use of EIS and DRT can be employed to identify when the sodiation capacity of the carbon is reached and metallic sodium plating commences, by observing the size/area of the respective peak. This is particularly interesting in a full cell setup, where in a “healthy” cell no bulk sodium is present and therefore the appearance of an electroplating signal in the DRT should be seen immediately. This method could hence facilitate online monitoring of a cell.

Generally, the kinetics of the sodiation and desodiation are similar to each other where the desodiation proceeds in reverse order to the sodiation.

Lastly, it should be noted that the long-term stability of the structures formed during the plateau phase of the sodiation is questionable and probably less affected by frequent cycling than by long storage times at high states of charge. Temperature and material dependence of the stability should be considered, as the underlying processes such as Ostwald-ripening are highly temperature dependent.

## Modelling upon the DRT results

To explain and illustrate the DRT results of the sodiation process by parameters with a physical meaning, the development of a

suitable equivalent circuit model is inevitable. This model has to capture both, mass transport and electrode kinetics, for the sodium and the hard carbon electrode simultaneously.

Furthermore, it has to be constructed from a reasonable amount of circuit elements in order to retain the physical relevance and to avoid overfitting.

One possible equivalent circuit model, which we propose herewith, is depicted in Fig. 7. The sodium side of a full cell is therein described by a single charge transfer resistance which is connected in series with a planar finite transmissive Warburg element to account for the diffusion of sodium ions through the separator. This serial connection of resistances is in turn connected in parallel to a capacitor which accounts for the electrochemical double-layer capacity (Fig. 7, left hand side). The C-side (right hand side of Fig. 7) is in turn modelled by parallel connection of (a) a serial connection of a charge transfer resistance and a planar finite transmissive Warburg element at the boundary electrode/separator, (b) a charge transfer resistance in combination with a planar finite reflective Warburg element which accounts for the diffusion inside of the carbon and (c) a capacitor to account for the double layer capacity of the carbon. In case of (c), the double layer capacity cannot be subdivided into one part belonging to the finite and one belonging to the semi-infinite diffusion branch, since capacities connected in parallel unify to one capacity.

Though, the assumption of a planar finite reflective Warburg element (analogue to a thin layer cell) is certainly not ideal for quantitatively describing a porous hard-carbon electrode which consists of almost any kind of pore shapes, sizes and geometries, a qualitative approximation will still be possible. This is justified by the fact that any kind of finite-length diffusion will share the feature of an interrupted mass transfer in a reflective diffusion domain. At this stage it is therefore exceptionally worth to note that all of the following derivations and remarks do particularly not intend to provide a quantitative interpretation of the actual

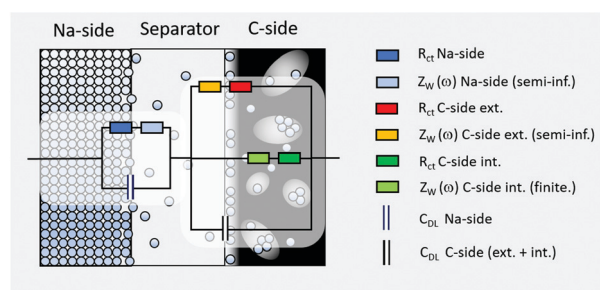

Fig. 7 Equivalent circuit model for the sodiation process of the Na/C cell. The Na-side is described by a single charge transfer resistance in series with a planar semi-infinite Warburg element to account for the diffusion through the separator (electrolyte). These two resistances are in turn connected in parallel to a capacitor which accounts for the electrochemical double-layer capacity. The C-side is described by parallel connection of (a) a serial connection of a charge transfer resistance and a planar semi-infinite Warburg element at the boundary electrode/separator, (b) a charge transfer resistance in combination with a finite length Warburg element to account for the diffusion inside of the carbon and (c) a capacitor to account for the double layer capacity of the carbon.

electrode kinetics. Instead, they should serve as a physical and mathematical supplement to the experimental results and a support for the proposed model. If one wished to quantitatively characterize the electrode kinetics, another—yet much more decent—model which captures the actual electrode porosity will be mandatory. However, developing such a model is certainly beyond the scope of this paper.

### Setting up the model

The overall impedance of the equivalent circuit depicted in Fig. 6 is given by

$$Z_{\text{tot}} = Z_{\text{Na,T}} + \frac{Z_{\text{C,R}}Z_{\text{C,T}}}{Z_{\text{C,R}} + Z_{\text{C,T}}} \quad (14)$$

where  $Z_{\text{tot}}$  is the overall impedance,  $Z_{\text{Na,T}}$  is the impedance of the sodium side (index T for transmissive) and  $Z_{\text{C,R}}$  and  $Z_{\text{C,T}}$  are the impedances of the carbon side which include either a planar finite transmissive (index T) or a planar finite reflective (index R) Warburg element, respectively.

Defining the faradaic impedance as the combination of Warburg impedance and charge transfer resistance, one can rewrite the individual impedances ( $Z_{k,l}$  with  $k,l = \text{C,R}; \text{C,T}; \text{Na,T}$ ) as

$$Z_{k,l} = R_{\text{sol}} + \frac{1}{\frac{1}{Z_{\text{Far},k,l}} + j\omega C_k} \quad (15)$$

where  $R_{\text{sol}}$  is the Ohmic resistance of all the system components  $C_k$  is the capacity,  $j = \sqrt{-1}$  and  $Z_{\text{Far},k,l}$  is the faradaic impedance of component  $k$ . For the transmissive elements it is defined as

$$Z_{\text{Far},k,l=\text{T}} = \frac{RT}{An^2F^2} \left( \frac{1}{\alpha k_{\text{f}}c_{\text{r}} + (1-\alpha)k_{\text{b}}c_{\text{o}}} \right) \times \left\{ 1 + \frac{1}{\sqrt{j\omega D}} \left[ k_{\text{f}} \tanh \left( d\sqrt{\frac{j\omega}{D}} \right) + k_{\text{b}} \tanh \left( d\sqrt{\frac{j\omega}{D}} \right) \right] \right\} \quad (16)$$

and for the reflective elements as

$$Z_{\text{Far},k,l=\text{R}} = \frac{RT}{An^2F^2} \left( \frac{1}{\alpha k_{\text{f}}c_{\text{r}} + (1-\alpha)k_{\text{b}}c_{\text{o}}} \right) \times \left\{ 1 + \frac{1}{\sqrt{j\omega D}} \left[ k_{\text{f}} \coth \left( d\sqrt{\frac{j\omega}{D}} \right) + k_{\text{b}} \coth \left( d\sqrt{\frac{j\omega}{D}} \right) \right] \right\}. \quad (17)$$

In eqn (16) and (17),  $\tanh(x)$  and  $\coth(x)$  represent the hyperbolic tangent and hyperbolic cotangent functions respectively. Furthermore,  $\alpha$  stands for the electron transfer coefficient,  $D$  for the diffusion coefficient of the electrochemically active species (in either the separator or the hard-carbon matrix),  $d$  for the diffusion domain size,  $A$  for the total electrode area,  $c_{\text{r}}$  and  $c_{\text{o}}$  for the concentration of reduced and oxidized species according to the Nernst-Potential and  $k_{\text{f}}$  and  $k_{\text{b}}$  are the potential

dependent rate constants according to the Butler–Volmer model. These are defined by

$$k_{\text{f}} = k^0 \exp \left( \frac{\alpha nF(E^{\text{eq}} - E^0)}{RT} \right) \quad (18)$$

$$k_{\text{b}} = k^0 \exp \left( \frac{-(1-\alpha)nF(E^{\text{eq}} - E^0)}{RT} \right) \quad (19)$$

In eqn (18) and (19),  $k^0$  is the standard rate constant with the units of  $[\text{cm s}^{-1}]$ , the variables  $n, F, R, T$  have their usual meaning.

Generating impedance data of the base of eqn (14) can be performed readily by invoking eqn (15)–(19). The most crucial point is then the careful and reasonable choice of the parameters utilized for the simulations. Following this strategy, we have generated a set of EIS data which reproduces the experimentally observed peak drift in the DRT representation of the sloping region during the sodiation process. The respective experimental and simulated data is depicted in Fig. 8. The set of parameters used for the simulation is given in Table S1 (ESI<sup>†</sup>). Based on the qualitative model, the experimentally obtained features in the DRT might be explained as follows.

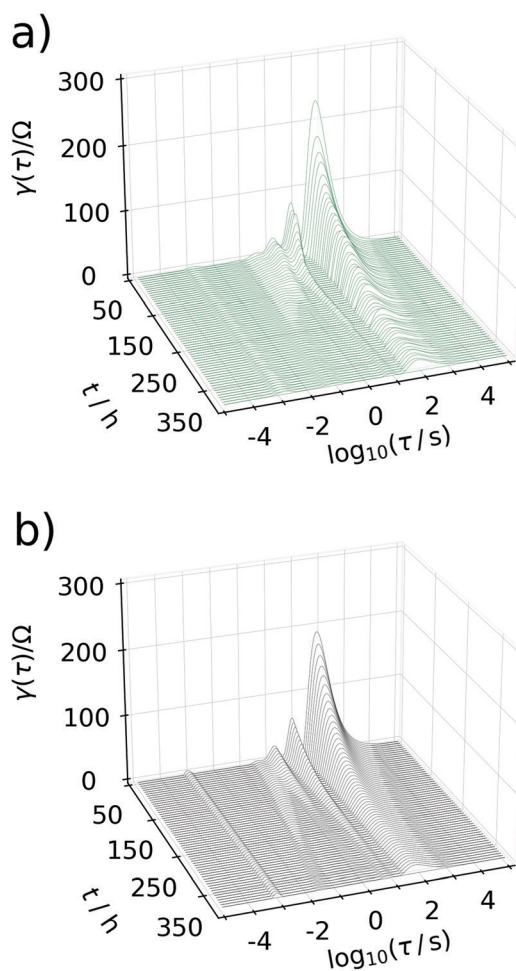

Fig. 8 Waterfall plot comparing the DRTs calculated between 50 h and 350 h. In (a) experimental data are depicted, (b) shows DRTs calculated from simulated data assuming the model described in Fig. 7.

At the beginning of the sodiation process, only a very low amount of sodium from former charge/discharge cycles is left inside of the carbon electrode. Consequently, the faradaic impedance (diffusion and charge transfer) of the carbon side will dominate the overall impedance owing to a low concentration of electrochemically active species. With an increasing degree of sodiation this particular resistance will decrease since (a) the amount of sodium inside of the electrode most likely located in the SEI increases progressively and, particularly, (b) the electrode potential will get closer to the  $E^0$ . Since the electrode potential is related to the resistances in an exponential manner, only small changes in the difference of equilibrium potential and  $E^0$  will enforce a significant change in the resistance. Therefore, adjusting the equilibrium potential more towards  $E^0$  results in a significant decay of the peak related to the faradaic impedance at the beginning of the sodiation and previous to the sloping region. As the sodiation process continues, the carbon electrode will get progressively filled with sodium. However, the non-exponential potential drift in the sodiation curve which emerges in the sloping region cannot be explained in terms of a standard Nernstian system. It might be described accurately, by considering that the  $E^0$  of the carbon electrode can also adjust with an increasing degree of sodiation. This assumption appears to be reasonable, since an increasing degree of sodiation might be interpreted alternatively as a non-equilibrium phase transition and the resulting Na/C phase will possess its own and distinct  $E^0$  value. In this manner, an almost linear potential drift results, which was utilized in turn for the simulations. It shall not be left unnoticed that the frequency shift of the peak can only be reproduced, if the concentration of sodium in the carbon phase is assumed about three orders of magnitude smaller than it is estimated from Faraday's second law. It indicates that not all of the reversibly bound sodium is forming a Na/C phase, but electrodeposition of metallic sodium in carbon pores and other suitable sites of the material is more likely to start towards the end of the sloping phase.

The major, experimentally observed, feature which was reproduced by the simulation is the peak splitting and the peak drift in the DRT. This particular observation can be explained as follows. As the degree of sodiation in the carbon side increases, the individual resistances belonging to the reflective and the transmissive faradaic impedance will behave inherently different in the diffusive, but similar in the charge transfer part. As an increasing degree of sodiation decreases both resistances, the relative peak height in the DRT will decay. However, as soon as reflective diffusion path starts to block the current from flowing, the resistance will be governed more and more by the transmissive branch (since the carbon side is considered as a parallel connection of a transmissive and a reflective branch). At exactly this point, the peak splitting in the DRT will start. Since the equilibrium potential will adjust progressively towards the  $E^0$  of sodium with an increasing degree of sodiation, the remaining transmissive branch of the carbon side will also tend towards the peak associated with the sodium side which finally explains the drifting peak and concludes our remarks on the sloping region.

## Conclusion

Electrochemical impedance spectra measured during the sodiation and desodiation of a hard carbon anode were investigated by means of DRT analysis. Generally, sodiation and desodiation were found to proceed *via* analogous pathways in a reverse order, therefore the following statements apply to both procedures. Spectra obtained during the sloping region of the sodiation curve were found to be largely dominated by diffusion processes, which became less relevant or simpler the more sodium was accommodated in the hard carbon. A constant DRT profile was observed during the plateau region. Upon exceeding the sodiation limit of the anode, the onset of electroplating could be followed in the DRT, rendering the method potentially useful to identify the formation of bulk sodium dendrites in full cells in equilibrium under practically relevant conditions.

Finally, an equivalent circuit model based on the results gained from the DRT analysis could be set up and was used to simulate impedance data during the sloping region between 50 and 350 h.

Although the model is inherently qualitative, the processes, as well as their trends over time could be reproduced with sufficient precision. By choice of appropriate fit parameters, it was concluded that the deposition of sodium in appropriate sites of the carbon is the main process occurring during the plateau phase. In the next steps, it would be promising to validate the assignment of processes to DRT-features, which can only be realized by the combination with *in situ* methods. By acquisition of impedance data of anodes sodiated to several SOCs and *in situ* or even better *operando* measurement of NMR spectra it should be possible to follow the change of chemical shift and therefore the oxidation state of sodium.<sup>18,27</sup> Small-angle X-ray scattering performed on such samples could furthermore provide valuable information on the region, where sodium is deposited within the electrode.<sup>22,57,58</sup> With such a study, an entire view on the sodiation process of hard carbons can be proposed and afterwards EIS/DRT could be used to characterize the sodium storage mechanism of a hard carbon on a laboratory but also industrially more relevant scale. The calculation of a DRT from impedance data not only provides valuable insights into the sodiation mechanism of hard carbon anodes, but also provides guidelines for the tailored design of high-capacity sodium storage materials, as well as their electrochemical characterization.

## Experimental section

Hexaazatriphenylenehexacarbonitrile (HAT-CN) was synthesized following the procedure of Rademacher *et al.*,<sup>56</sup> in order to serve as the precursor for the preparation of the carbon material under study. HAT-CN was directly carbonized in a horizontal tube furnace under argon atmosphere according to the method of Walczak *et al.*<sup>53</sup> In particular, HAT-CN was first heated to 60 °C at a heating rate of 4 °C min<sup>-1</sup> and held for 30 min. In the second heating step, the material was at the same rate heated to the target temperature 1000 °C. Subsequently, the material was

transferred to a high-temperature horizontal tube furnace and subjected to another heat treatment in an Ar atmosphere at 1600 °C for 60 min with a heating ramp of 3 °C min<sup>-1</sup>. It was denoted C-HAT-1600, 1600 indicating its final carbonization temperature.

Gas physisorption measurements were conducted on a Vapor200C analyzer by 3P Instruments with Ar at -186 °C, and CO<sub>2</sub> at 0 °C as probe gases. The samples were degassed under vacuum at 150 °C for at least 20 h before each measurement.

Specific surface areas were calculated from the adsorption branch by the multipoint BET-method in a  $p/p_0$ -range of 0.01–0.15. Pore size distributions were calculated by quenched solid density functional theory (QSDFT) from the adsorption branch for slit/cylindrical shaped carbon pores, provided in the ASiQWin software package by Quantachrome Instruments. The nitrogen content was determined from combustive elemental analysis (EA) on a MICRO CHNS analyzer by elementar.

For the electrochemical characterization, the carbon material was fabricated into an ink by grinding it together with carbon black (SuperP, Alfa Aesar) as the conductive additive and adding an aqueous solution of carboxymethylcellulose (Sigma) as the binder in the ratio of 8 : 1 : 1 of the respective components. The ink was dispersed in an ultrasonic bath for 1 h and stirred overnight, before it was coated on copper foils of 10 mm in diameter to achieve an area loading of approx. 1 mg cm<sup>-1</sup>. Electrochemical parameters obtained with such electrodes typically vary within 5% error.<sup>54</sup> The impact of SuperP accounts to less than 5% of the capacity and therefore was neglected during the study in favour of the advantages it provides for the electrode conductivity.<sup>59</sup> A 1 M solution of NaPF<sub>6</sub> in a 6 : 4 v/v mixture of ethylene carbonate and diethyl carbonate was used as the electrolyte. Potentials are always referred to as against Na/Na<sup>+</sup>, unless otherwise stated.

The electrochemical measurements were performed in 2-electrode Swagelok-type cells on a BioLogic MPG-2 potentiostat. Cells were assembled in asymmetrical setup of active material *vs.* sodium, and symmetrical cells with sodium *vs.* sodium in order to assign the processes to the respective half-cell reaction.

Charge discharge curves were recorded in different modes using (a) voltage limitation between 2.5 V and 0.002 V and (b) a lower capacitance limit of 85% of the previously determined plating capacity. The latter enables capacities at voltages below 0 V to be considered as well and hence losses due to overpotentials are overcome.

The measurement routine to obtain EIS data for DRT analysis consisted of 5 initial charge discharge cycles, after which the cell was fully desodiated to 2.5 V and left to rest for 30 min. Next, a current pulse of 18.6 mA g<sup>-1</sup> was applied to the cell for 10 min, followed by a resting period of 5 h, to obtain a steady potential for the subsequent EIS at 10 mV amplitude in a frequency range from 20 kHz to 10 mHz with 11 frequencies per decade. The three steps of current pulse, rest, and EIS were repeated until and beyond the maximum sodiation of the working electrode, characterized by a crystallization overpotential due to the nucleation of bulk sodium.
