The urgent need for a stable, efficient, and affordable oxygen evolution reaction (OER) catalyst has led to the investigation of a vast amount of transition metal materials with multiple different anions. *In situ* and *post* catalytic characterization shows that most materials transform during the harsh OER conditions to layered (oxy)hydroxides (LOH). Several open questions concerning these *in situ* formed LOH remain such as: an explanation for their strongly varying activities, or the effect of the precatalyst structure, leaching anions, and transformation conditions on the formed LOH. Herein, we report on a cobalt selenite precursor, which, depending on pH and potential, transforms irreversibly into two different LOH OER catalysts. Combining multiple electrochemical and analytical methods *ex* and *in situ*, we prove that one of these products is near-surface catalytically active and the other one throughout the bulk with an *in situ* average cobalt oxidation state of 3.2. We deduce a detailed structural model explaining these differences and propose general concepts relating both the precatalyst structure and the transformation conditions to the final catalyst. Further, we apply these models to the most promising non-noble metal catalyst, NiFe LOH.

## Broader context

Implementing a sustainable global energy economy requires more than the construction of solar and wind power plants, as the fluctuations of these energy sources contrast the constant energy demand of society. A solution to this problem is a highly scalable energy storage technology. In this regard, fuels are advantageous as, for their scalability, only simple tanks must be constructed instead of highly resource-/energy-demanding batteries. Fuels contain reduced chemical species that can be burned using O<sub>2</sub> under the release of energy. To close this energy storage cycle, oxidized compounds must be reduced while investing electric energy. The electrons for this process come from water (O<sup>-II</sup>) independent of whether the oxidized species are CO<sub>2</sub> or protons. Therefore, catalytic oxygen evolution (OER) is the central process to form regenerative fuels from green electricity. The harsh conditions during OER lead to an *in situ* transformation of most materials. Herein, we introduce a new concept to understand this transformation while considering the substrate and the transformation conditions. Our detailed *ex*- and *in situ* investigations allow us to deduce structural relationships explaining different activities in layered double hydroxides, the most promising catalysts for the alkaline OER.

## Introduction

Highly scalable energy storage technologies are required for the implementation of a sustainable global energy economy.<sup>1–3</sup> In this regard, green fuel formation out of water and CO<sub>2</sub> is highly promising.<sup>4–7</sup> For fuel formation processes, electrons are required.<sup>8</sup> The most prominent reaction supplying electrons is the oxygen evolution reaction (OER), where electric energy is used to oxidize abundant O<sup>-II</sup> (from water).<sup>8–10</sup> The kinetically demanding OER involves four sequential proton-coupled electron transfer steps and accounts for a significant loss of efficiency in

fuel forming processes.<sup>11,12</sup> To overcome this disadvantage, a vast amount of suitable OER catalysts based on earth-abundant transition-metals (TM) has been investigated.<sup>9,13</sup> Initially, mainly (Fe/Co/Ni) $O_xH_y$  were explored.<sup>14</sup> However, research has shown that varying the anion can be advantageous.<sup>15</sup> In this regard, chalcogenides,<sup>16</sup> pnictides,<sup>17</sup> carbides,<sup>18</sup> borides,<sup>19</sup> phosphates,<sup>20</sup> phosphites,<sup>21</sup> borates,<sup>22</sup> borophosphates,<sup>23</sup> and intermetallic materials<sup>24</sup> have been tested for their suitability as OER electrode materials.<sup>9,15,25</sup>

The TM compounds with these anions are expected to transform under industrially relevant OER conditions (pH > 14, current densities above 200 mA cm<sup>-2</sup> and lifetimes up to 100 000 h) as their anions either have redox potentials significantly lower than those of O<sup>-II</sup> or are highly soluble in water.<sup>25-27</sup> *In situ* and post catalytic characterization methods revealed that, even within a few hours at low current densities (10 mA cm<sup>-2</sup>) and pH 14, most of these materials undergo corrosion.<sup>18,23,24,28-38</sup> Therefore, they are merely precatalysts, and the active species are in most cases Fe/Co/Ni layered (oxy)hydroxides (LOH). The observed transformations are consistent with the Pourbaix diagrams of iron, cobalt, and nickel (shown in Fig. S1, ESI<sup>†</sup>), as they reveal that LOH are the only thermodynamically stable oxide phases under OER conditions besides dissolved FeO<sub>4</sub><sup>2-</sup>.<sup>39-42</sup>

Thus, during the OER, a precatalyst transforms into the active-state catalyst (see Scheme 1). The nature of this catalyst will depend on the structure of the precatalyst and on the leaching ability, redox potential, and size of its anion.<sup>25,26,31</sup> Further, the transformation conditions (mainly pH and electrical potential) will affect the structure and catalytic properties of the active-state catalyst. In this regard, it has been shown that from one precatalyst, depending on the applied *V*, an OER or hydrogen evolution reaction (HER) catalyst with different structures and electronic properties can be formed.<sup>20,23,35,36</sup> However, even though many OER precatalysts have been investigated already, the influence of the precatalyst structure, the leaching anion, and the transformation conditions on the eventually formed LOH catalyst remains as an open question.<sup>31,34,43</sup>

Although LOH share the same short-range order (layers of edge-sharing MO<sub>6</sub> octahedra, see Fig. 1 left), they are structurally highly versatile, as the organization of these layers varies drastically.<sup>44</sup> In crystalline forms, the layers are usually stacked in parallel (see Fig. 1 middle). Between the layers, neutral and charged species can be intercalated, affecting the layer distance.<sup>45</sup> The layers do not have to be perfectly planar and can be bend.<sup>46</sup> Furthermore, amorphous forms exist, where single layers (domains) are only a single or very few nanometers in diameter and the stacking is disordered (see Fig. 1 right).<sup>47-49</sup> The domains can be connected by tetrahedral units or electrostatic

Fig. 1 Structural models for LOH. Left: Top view on a layer of edge sharing [MO<sub>6</sub>] octahedra, the common structural motif of LOH. Centre: A crystalline LOH with parallel stacking of the layers. Right: An amorphous LOH with disordered layer arrangement.

interactions.<sup>48</sup> These structural variations (tetrahedral linkage of domains, domain size, domain stacking, defects, doping...) of amorphous LOH are pivotal for their catalytic properties and can help to understand the substantially different OER performance of *in situ* formed LOH.<sup>23,25,26,30,31,48,50</sup> Because the structural variations are non-periodic and highly complex, the elucidation of structure-performance relationships is challenging,<sup>51</sup> and raises the following research questions:

- Does the variation of pH and *V* afford different LOH OER catalysts from the same precatalyst?
- How do structural variations of amorphous LOH affect their catalytic performance?
- Can the structure of the LOH catalyst be predetermined by that of the precatalyst?
- Why are *in situ* formed LOH from precatalysts with leaching anions often more active than directly synthesized ones?

To answer these questions, we focused on monometallic cobalt LOH as a suitable system, as it combines a high catalytic activity per active site with sufficient conductivity and good stability under alkaline OER conditions.<sup>52,53</sup> For the precatalyst structure, a preorganization of the cobalt in layers similar to the final LOH is desired, as this may simplify to determine structural correlations between the precatalyst and catalyst. Further, if the anion is located in the interlayer space, a rapid leaching could be beneficial for the complete transformation in cobalt LOH. Cobalt(II) selenite, CoSeO<sub>3</sub>·H<sub>2</sub>O, crystallizing in the space group *P*2<sub>1</sub>/*n*, fulfills these requirements and has never been tested as an OER precatalyst.<sup>54-56</sup> It acquires a layered structure with a layer spacing of 6.6 Å (see Fig. 2).<sup>‡</sup> The layers are comprised of [CoO<sub>6</sub>] octahedra sharing four corners. The [CoO<sub>6</sub>] octahedra are additionally connected *via* [SeO<sub>3</sub>] units with selenium pointing into the interlayer space. Moreover, coordinated water resides between the [CoO<sub>6</sub>] layers. Further, CoSeO<sub>3</sub>·H<sub>2</sub>O contains Se<sup>IV</sup>, which could be an intermediate in the *in situ* transformation of TM selenides to the corresponding LOH,<sup>26</sup> that show outstanding OER performances as reported recently.<sup>29,50,57-61</sup>

Herein, we demonstrate that, depending on the pH and *V*, two cobalt LOH with very different catalytic properties can be

Scheme 1 Transformation of a precatalyst to the active catalyst. The reversible step on the right side shows the dynamic behavior of the catalyst, which can be assessed by *in situ* investigations.

‡ The correct formula of the compound would be Co(H<sub>2</sub>O)[SeO<sub>3</sub>], as the water coordinates to the cobalt and is not crystal water. However, we refer to it as CoSeO<sub>3</sub>·H<sub>2</sub>O to be consistent with previous reports.

Fig. 2 Crystal structure of  $\text{CoSeO}_3 \cdot \text{H}_2\text{O}$ . Selenium in green, oxygen in red, hydrogen in grey, and  $[\text{CoO}_6]$  octahedra in purple. formed *in situ* from the  $\text{CoSeO}_3 \cdot \text{H}_2\text{O}$  precatalyst; one is bulk OER-active and the other active only in its near-surface region. Through detailed quasi *in situ* and post catalytic investigations, we deduced a model explaining the different catalytic properties of LOH phase with the same short-range but different long-range orders, and propose a concept relating the precatalyst structure and the transformation conditions to the active catalyst.

## Results

$\text{CoSeO}_3 \cdot \text{H}_2\text{O}$  was obtained through a facile, previously reported, hydrothermal synthesis from  $\text{SeO}_2$  and  $\text{Co}(\text{OAc})_2$  and characterized by state of the art methods: light microscopy (see Fig. 3 and Fig. S2, ESI<sup>†</sup>), scanning electron microscope (SEM) with energy dispersive X-ray (EDX) mapping (see Fig. 3 and Fig. S3, ESI<sup>†</sup>), powder X-ray diffraction (pXRD, see Fig. S4, ESI<sup>†</sup>), inductively coupled plasma optical absorption spectroscopy (ICP-OES, see Fig. S4, ESI<sup>†</sup>), X-ray photoelectron spectroscopy (XPS; see Fig. S5, ESI<sup>†</sup>), transmission electron microscopy (TEM) with selected area electron diffraction (SAED, see Fig. S6, ESI<sup>†</sup>), resonance Raman (RR, see Fig. 9), and X-ray absorption spectroscopy including extended X-ray absorption fine structure (EXAFS; see Fig. 10) and X-ray absorption near edge structure (XANES; see Fig. 10) analyses. All methods confirm the formation of a pristine  $\text{CoSeO}_3 \cdot \text{H}_2\text{O}$  phase with no additional surface oxidation.

Fig. 3 Left: Light microscope image showing the needle like morphology of  $\text{CoSeO}_3 \cdot \text{H}_2\text{O}$ , right: SEM/EDX mapping of the tip of a needle of  $\text{CoSeO}_3 \cdot \text{H}_2\text{O}$  revealing a homogeneous distribution of the elements (for EDX spectrum see Fig. S3, ESI<sup>†</sup>).

## Alkaline OER investigations

Performing cyclic voltammetry (CV) with  $\text{CoSeO}_3 \cdot \text{H}_2\text{O}$  deposited on fluorine doped tin oxide (FTO), we observed a broad redox feature during the first cycle, indicating a transformation of the material (see Fig. S9(a), ESI<sup>†</sup>). Further, the purple film turned black during the first CV (see Fig. S9(a) and (b), ESI<sup>†</sup>). In the second CV a current density ( $i$ ) of  $10 \text{ mA cm}^{-2}$  was reached at an overpotential ( $\eta$ ) of 332 mV (see Fig. S9(b), ESI<sup>†</sup>). Interestingly, a color change was already observed, when the film was exposed to the 1 M KOH for 60 s without applied potential (see Fig. S9(c), ESI<sup>†</sup>). pXRD revealed that after 60 s a phase with low crystallinity formed while after 1 h a crystalline one was obtained (see Fig. S9(d), ESI<sup>†</sup>). Based on these observations, we decided to investigate two different transformation pathways for the *in situ* formation of an OER catalyst from the  $\text{CoSeO}_3 \cdot \text{H}_2\text{O}$  precursor (see Fig. 4). The first one was a two-step process, where the precatalyst was first exposed to 1 M KOH for 1 h (Co-KOH) and subsequently for 1 h a potential of 1.56 V *vs.* reversible hydrogen electrode ( $V_{\text{RHE}}$ ) was applied (Co-KOH-V). In the second pathway, the same precatalyst was directly exposed to 1.56  $V_{\text{RHE}}$  for 1 h in the alkaline solution (Co-V).

**Electrochemical transformation and CV.** Fig. 5(a) shows the current responses at 1.56  $V_{\text{RHE}}$  for the two pathways. Both curves exhibit an initial peak and then approach asymptotically to a certain current density. We ascribe the current peak to the precatalyst oxidation and the asymptotic current to the OER. The OER current of the Co-V electrode was around 15 times higher than that of Co-KOH-V. Additionally, we investigated the CA response at different potentials as well as at pH 13 and 12 (see Fig. S10(a)–(d), ESI<sup>†</sup>). We found that both a pH above 13 and a redox potential above the  $\text{Co}^{\text{II/III}}$  redox feature are required for a large current response and high OER activity as observed for Co-V. For a CA measurement at 1.24  $V_{\text{RHE}}$ , the integration of the oxidation peak revealed that about three electrons per formula unit were removed from the sample (see Fig. S10(e), ESI<sup>†</sup>). This finding is consistent with the oxidation of  $\text{Co}^{\text{II}}$  to  $\text{Co}^{\text{III}}$  and  $(\text{Se}^{\text{IV}}\text{O}_3)^{2-}$  to  $(\text{Se}^{\text{VI}}\text{O}_4)^{2-}$ . This hypothesis also explains why a redox potential above the  $\text{Co}^{\text{II/III}}$  redox feature is required for a large current response. For Co-KOH-V, only 0.25 electrons per formula unit were removed, indicating an incomplete oxidation or surface oxidation of the precatalyst

Fig. 4 Scheme of the deposition and the two herein presented transformation pathways with the names of the obtained compounds and intermediates (KOH represents 1 h of KOH exposure and V 1 h at  $\eta = 310 \text{ mV}$ ). The obtained  $\text{CoSeO}_3 \cdot \text{H}_2\text{O}$  film was examined by SEM/EDX and EXAFS (see Fig. S7, S8, S29, and Table S2, ESI<sup>†</sup>).

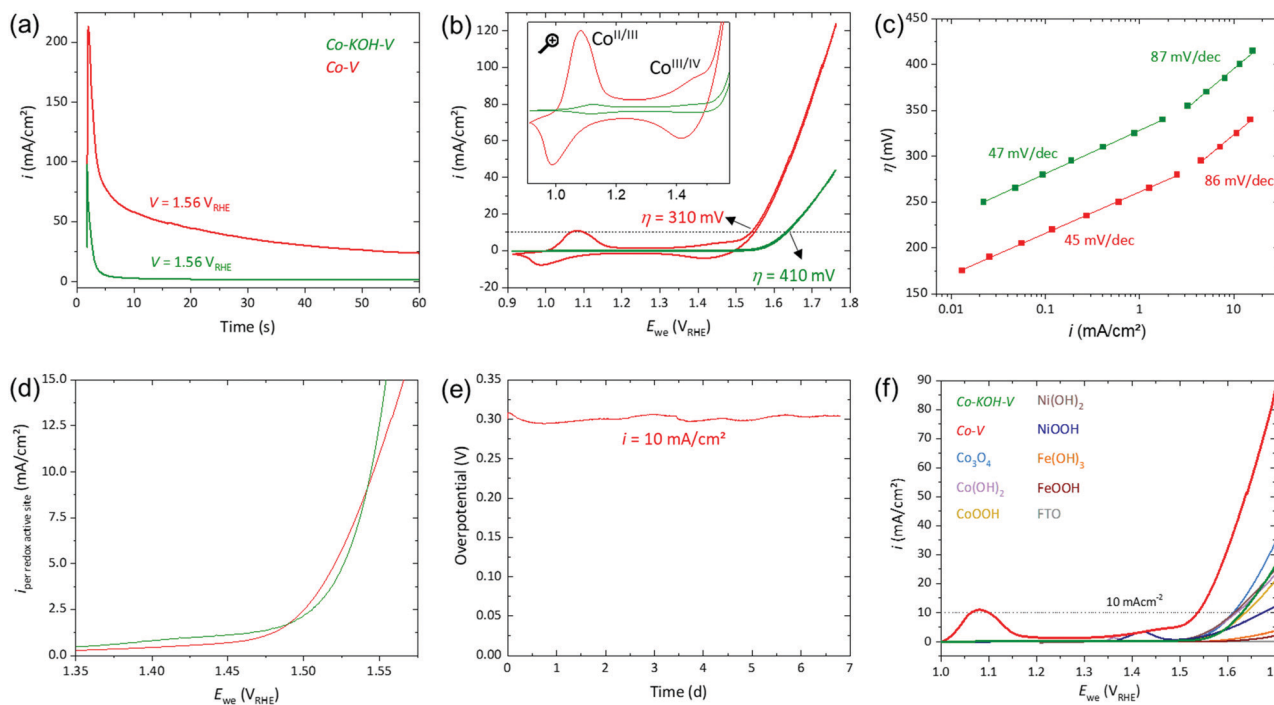

Fig. 5 Electrochemical investigations on FTO substrates of Co-KOH-V (in green) and Co-V (in red; both: loading 4  $\mu\text{mol}$ , area 1  $\text{cm}^2$ ). (a) Current responses at 1.56  $V_{RHE}$ . (b) CV ( $\nu = 5 \text{ mV s}^{-1}$ ) with a magnification of the redox peaks as inset. (c) Steady-state Tafel analyses. (d) Current densities taken from CV ( $\nu = 1 \text{ mV s}^{-1}$ ) normalized by the amount of  $\text{Co}^{II/III}$  redox active sites. (e) CP measurement of Co-V at 10  $\text{mA cm}^{-2}$ . (f) LSVs ( $\nu = 5 \text{ mV s}^{-1}$ ) of several  $(\text{Co}/\text{Ni}/\text{Fe})\text{O}_x\text{H}_y$  compounds in comparison to Co-KOH-V and Co-V. All measurements have been iR compensated (see ESI† for details).

(see Fig. S10(f), ESI†). All following electrochemical or analytical investigation were performed after 1 h of chronoamperometry (CA) at 1.56  $V_{RHE}$  for both samples.

The CVs in Fig. 5(b) reveal that the electrocatalytic activity of Co-V ( $\eta_{10} = 310 \text{ mV}$ ) was considerably higher than that of Co-KOH-V ( $\eta_{10} = 410 \text{ mV}$ ). Further, for both samples, two well-separated reversible redox peaks are present (see inset Fig. 5(b)). These reversible features are the  $\text{Co}^{II/III}$  and  $\text{Co}^{III/IV}$  redox processes.<sup>49,62</sup> They remained unchanged when the electrolyte was changed to fresh selenium free 1 M KOH. Both redox peaks of Co-V are several times larger than those of Co-KOH-V. Integration of the  $\text{Co}^{II/III}$  peak of Co-V disclosed that more than 40% of the cobalt atoms underwent this reversible transformation (for the integration of all redox peaks see Fig. S11, ESI†). For Co-KOH-V, it was fewer than 3% of the cobalt. For the  $\text{Co}^{III/IV}$  redox peak of Co-V, approximately 30% of the total cobalt sites were redox active (2.5% for Co-KOH-V).

The peak current of a redox transition in CV is a function of the scan rate ( $\nu$ ). For a (pseudo)capacitive redox process, the peak current is proportional to  $\nu$ .<sup>63,64</sup> Limitations by transport phenomena lead to a deviation of this behavior ( $\nu$  for a diffusion controlled process). In Fig. S12 (ESI†), the peak current of the  $\text{Co}^{II/III}$  redox feature is plotted against  $\nu$ ; for Co-V and Co-KOH-V, a linear relationship is obtained. Therefore, neither diffusion of base nor electron transport is significantly limiting at the investigated current densities (up to 20  $\text{mA cm}^{-2}$ ). This is consistent with reported *in situ* conductivity measurements on cobalt oxyhydroxides.<sup>65,66</sup>

**Tafel analysis,  $C_{dl}$ , EIS, long term CA, and LSV.** Fig. 5(c) shows steady-state Tafel plots with two linear regions with the same slope for both catalysts. The first slope is around 46  $\text{mV dec}^{-1}$  and the second around 86  $\text{mV dec}^{-1}$ . As both systems, Co-V and Co-KOH-V, have the same two Tafel slopes, it is likely that the active-site structures and catalytic mechanism are identical. Consequentially, the reaction rates per active site should be alike. Thus, we conclude that a larger number of catalytically active cobalt sites explains the improved performance of Co-V. Cobalt sites that can undergo the reversible  $\text{Co}^{II}-\text{Co}^{III}-\text{Co}^{IV}$  redox processes potentially fulfill the requirements to be a catalytically active site.<sup>49,66,67</sup> Therefore, integration of the isolated  $\text{Co}^{II/III}$  redox peak at 1.05  $V_{RHE}$  can approximate the amount of catalytically active cobalt sites. Fig. 5(d) displays the activity of Co-KOH-V and Co-V normalized by the amount of  $\text{Co}^{II/III}$  redox active sites. The normalized activities are comparable. Hence, both catalysts have the same kind of catalytic sites, and the  $\text{Co}^{II/III}$  redox process is suitable for their quantification. We could not achieve an unambiguous estimation of the  $C_{dl}$  for the two catalysts. Nevertheless, all measurements indicate a significantly higher  $C_{dl}$  of Co-KOH-V compared to Co-V (see detailed discussion in Fig. S13, ESI†). This is consistent with the morphologies observed in the SEM and TEM for the respective samples (see Fig. S19, S20, S23 and S24, ESI†).

Electrochemical impedance spectroscopy (EIS) and long-term chronopotentiometric (CP) measurements were performed, as was linear scan voltammetry (LSV) in comparison to other

(Co/Ni/Fe) $O_xH_y$  compounds. EIS conducted at 1.55  $V_{RHE}$  yielded a semi-circular appearance in the Nyquist plot for Co-KOH-V and Co-V (see Fig. S14 (a), ESI $\dagger$ ). The diameter is approximately ten times smaller for Co-V, indicating a strongly reduced charge transfer resistance. A faradaic efficiency of 96% was measured for Co-V (see Fig. S14(b), ESI $\dagger$ ). A CP measurement at 10 mA  $cm^{-2}$  of Co-V yielded a stable performance for almost seven days (see Fig. 5 (e)). Various (Co/Ni/Fe) $O_xH_y$  were prepared and loaded in the same way on FTO. Fig. 5(f) shows LSVs recorded at 5 mV  $s^{-1}$  of the obtained electrodes together with Co-KOH-V and Co-V on FTO. This comparison reveals that the activity of Co-KOH-V is comparable to that of the other nickel- and cobalt-based phases. Surprisingly, Co-V is drastically more active than all the other materials. Furthermore, Co-V has a far stronger pronounced redox peak prior to the OER.

### Characterization of Co-KOH, Co-KOH-V and Co-V

**ICP-OES, XRD, SAED, and XPS.** The three compounds Co-KOH, Co-KOH-V, and Co-V synthesized as described in Fig. 4 were washed with demineralized water and subsequently investigated using various analytical methods. ICP-OES disclosed elemental ratios of Co:Se:K of 1:0.01:0.04, 1:0.01:0.10 and 1:0.04:0.50 for Co-KOH, Co-KOH-V, and Co-V, respectively. Therefore, selenium was depleted from  $CoSeO_3 \cdot H_2O$  in all three cases and oxidic cobalt species were formed.

Fig. 6 left depicts the pXRD patterns of the three samples taken directly from the FTO substrate. The diffractogram of Co-KOH exhibits all reflexes of crystalline  $\beta$ -Co(OH) $_2$  ( $P\bar{3}m1$ ,  $a = 3.18$  Å and  $c = 4.65$  Å, JCPDS 30-443). The three reflexes present for Co-KOH-V, were assigned to  $\beta$ -CoOOH ( $R\bar{3}m$ ,  $a = 2.85$  Å and  $c = 13.15$  Å, JCPDS 7-169). Co-V does not contain any diffraction peaks besides those of the FTO substrate. Hence, it is X-ray amorphous.

Electron diffraction is more sensitive than XRD and can disclose additional phases with a lower crystallinity. Fig. S15 (ESI $\dagger$ ) presents the SAED patterns of all three samples. The SAED of Co-KOH confirms the presence of  $\beta$ -Co(OH) $_2$  without additional diffraction spots. For Co-KOH-V, the SAED reveals the occurrence of not only  $\beta$ -CoOOH but also of low crystallinity  $\beta$ -Co(OH) $_2$ . The SAED of X-ray amorphous Co-V shows two

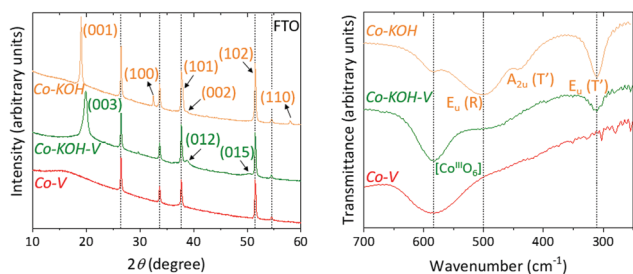

diffraction rings referring to lattice plane spacings of 2.42 Å and 1.41 Å, which could be assigned in the structural model derived from the EXAFS and HR-TEM data (see Fig. 8 and EXAFS part).

Fig. S16 (ESI $\dagger$ ) exhibits the XPS Co 2p and O 1s spectra of all three compounds. The post catalytic cobalt surface oxidation state is an approximately one-to-one mixture of Co $^{II}$  and Co $^{III}$  in all three materials. Such low surface oxidation states were previously observed for CoCat materials, which have higher bulk oxidation states.<sup>68</sup> The low surface oxidation states compared to the XANES investigations (see Fig. 10 left) could be related to a formation of  $Co_3O_4$  from the amorphous species.<sup>69</sup> The O 1s spectra show three species that were assigned to cobalt hydroxide as well as physis- and chemisorbed water.

**Transmittance infrared (IR) spectroscopy.** IR spectroscopy is an integrative, bulk sensitive method capable of distinguishing different amorphous and crystalline oxidic cobalt phases if performed at low wavenumbers. The IR spectra of the three samples are shown in Fig. 6 right. For Co-KOH, the three characteristic  $E_u$  (R),  $E_u$  (T'), and  $A_{2u}$  (T') modes of  $\beta$ -Co(OH) $_2$  ( $P\bar{3}m1$ ) are located at 500, 441, and 311  $cm^{-1}$ , respectively.<sup>70</sup> Additionally, a weak band at 582  $cm^{-1}$  is present. This band is characteristic for the octahedral coordinated Co $^{III}$  in CoOOH.<sup>71</sup> Thus, Co-KOH also contains small amounts of Co $^{III}$ , probably due to near-surface oxidation. The spectrum of Co-KOH-V strongly exhibits the characteristic band of CoOOH. Additionally, weak bands for the  $\beta$ -Co(OH) $_2$  phase are present, consistent with the SAED. For Co-V, only the vibration for octahedrally coordinated Co $^{III}$  is found. Fig. S17 (ESI $\dagger$ ) depicts the extended IR spectra from 4000 to 250  $cm^{-1}$ . For Co-KOH and Co-KOH-V, the characteristic  $\nu_{O-H}$  mode is present at 3622  $cm^{-1}$  in form of a sharp band, indicating a well-ordered hydroxide phase.<sup>70</sup> Interestingly, for Co-V, this vibration is absent and only a broad and very weak peak at 3420  $cm^{-1}$  is present suggesting a disordered hydroxide-containing material with a broad distribution of force constants. Another reason for the low intensity is a deprotonation of the hydroxide groups by KOH as expected from the Co Pourbaix diagram in Fig. S1 (ESI $\dagger$ ). The K to Co ratio of 1 to 2 from ICP-OES indicates that this is the case for half of the hydroxide groups. Further, for all compounds, no intense peaks indicating substantial amounts of  $(NO_3)^-$  or  $(CO_3)^{2-}$  intercalation are present.<sup>45</sup>

**Electron microscopy.** Fig. S18–S20 (ESI $\dagger$ ) show SEM images and EDX mappings of the three electrodes. For Co-KOH and Co-KOH-V, the SEM images reveal hexagonal nanoplates with a diameter of up to 1  $\mu m$ , which is typical for the formation of  $\beta$ -Co(OH) $_2$ .<sup>32</sup> For Co-V, SEM images do not show the formation of nanoplates, and particles of up to 10  $\mu m$  are present. The surface of the particles is rougher than in the  $CoSeO_3 \cdot H_2O$  material. In all three cases, the SEM-EDX spectra are consistent with the ICP-OES data (see Fig S21, ESI $\dagger$ ). The EDX mapping reveals a homogeneous distribution of cobalt and oxygen for all three samples (see Fig. S18–S20, ESI $\dagger$ ).

For Co-KOH and Co-KOH-V, TEM affirms the formation of hexagonal nanoplates (see Fig. S22 and S23, ESI $\dagger$ ). HR-TEM of Co-KOH unveils lattice spacings in accordance with the

**Fig. 6** Left: pXRD of Co-KOH, Co-KOH-V, and Co-V taken directly from the FTO substrate. The vertical dashed lines indicate the reflections of FTO. The oranges numbers are the millers indices of a  $\beta$ -Co(OH) $_2$  phase and the green ones of a  $\beta$ -CoOOH one. Right: IR spectra of the same compounds. The vibrations depicted in orange belong to a  $\beta$ -Co(OH) $_2$  phase.

Fig. 7 HR-TEM images with fast Fourier transforms as insets. Left: Image showing the layer stacking with the FFT of the white square revealing the layer spacing. Right: Image depicting nanocrystalline domains viewed from the top with the FFT unveiling lattice distances in the domains. The inset on the right top shows resolved single atom columns.

crystallographic planes (001), (100), and (022) of  $\beta$ -Co(OH)<sub>2</sub>. For Co-KOH-V, HR-TEM resolves lattice spacings in agreement with the crystallographic planes (100), (101), and (104) of  $\beta$ -CoOOH. HR-TEM with a LaBF<sub>6</sub>-cathode and a point resolution of around 240 pm could not resolve lattice fringes of Co-V. Therefore, spherical aberration corrected HR-TEM with a field emission gun cathode and a point resolution of 75 pm was applied (see Fig. 7 and Fig. S25, ESI<sup>†</sup>). Surprisingly, we could resolve single atom columns of crystalline domains in this X-ray amorphous material. The domains vary in size from one to five nanometers.

Fast Fourier transformation of these HR-TEM images reveals four lattice distances for Co-V. Two of them are identical to the ones of the SAED (see Fig. S15, ESI<sup>†</sup>). Fig. 8 shows a structural model of a layer of edge-sharing [CoO<sub>6</sub>] octahedra. The atomic distances of this structural model were derived from the EXAFS data (see below). All four HR-TEM lattice distances could be assigned to atomic planes of this structure. The atomic planes not present in the SAED refer to oxygen distances of planes parallel to the [CoO<sub>6</sub>] layers (see Fig. 8 right). As the layers do not stack in an ordered way, no periodicity in this diffraction

Fig. 8 Structural model of Co-V with the lattice distances from SAED/HR-TEM (grey lines) and the EXAFS coordination shells (white circles). On the left the top view on a domain with 51 cobalt atoms is presented and on the right the side view. This model contains 39%  $\mu_2$ -oxo bridged cobalt edge sites, which correlates well with the 40% of Co<sup>II/III</sup> redox active Co sites in Co-V.

direction is present. Thus, these atomic distances can only be resolved by HR-TEM and not by SAED. Another remarkable feature in the HR-TEM images is the presence of areas with fringes separated by approximately 8.9 Å (see Fig. 7 left and Fig. S25, ESI<sup>†</sup>). In these areas, the layered, molecular domains stack in parallel and are seen from the side. Therefore, 8.9 Å is the average layer distance for the parallel stacking. It is likely that domains with highly disordered stacking also exist and even in the areas with “parallel” stacking, the layer distances vary and structural disorders such as line defects are present (see Fig. 7 left).

Further, we investigated if additional morphological changes occur during longer OER testing of Co-V. In this regard, TEM and SEM images of a Co-V sample after 48 h at 10 mA cm<sup>-2</sup> were performed (see Fig. S26 and S27, ESI<sup>†</sup>). These images reveal that the morphology does not change significantly.

### Quasi *in situ* investigations

As illustrated in Scheme 1, the electrocatalytic system is highly dynamic and the actual catalyst structure might differ substantially from the one investigated after the OER reaction. Therefore, we performed quasi *in situ* investigations by freeze quenching (−196 °C) the electrodes during catalysis and kept them in liquid nitrogen until measurement. This freeze-quench approach was introduced and verified for similar systems.<sup>49</sup>

**Resonance Raman (RR) spectroscopy.** RR spectroscopy is *inter alia* a near-surface-sensitive method capable of distinguishing different amorphous and crystalline oxidic cobalt phases. Fig. 9 presents the RR spectra of deposited CoSeO<sub>3</sub>·H<sub>2</sub>O and Co-KOH together with the quasi *in situ* RR spectra of Co-KOH-V and Co-V. The spectrum of CoSeO<sub>3</sub>·H<sub>2</sub>O is dominated by a strong band that we assign to the symmetric stretching vibration of [SeO<sub>3</sub>].<sup>72</sup> This band is absent in all other spectra, confirming the selenium depletion in these compounds. Interestingly, the RR spectrum of Co-KOH is not

Fig. 9 RR spectra of CoSeO<sub>3</sub>·H<sub>2</sub>O and Co-KOH as well as *in situ* measured Co-KOH-V and Co-V.

consistent with the one of  $\beta\text{-Co}(\text{OH})_2$  but the one of  $\text{CoOOH}$  and the intensive peak at  $507\text{ cm}^{-1}$  corresponds to the Co–O–Co bending vibration ( $E_g$ ).<sup>73–76</sup> Therefore, bulk ( $\beta\text{-Co}^{\text{II}}(\text{OH})_2$ ; see pXRD, IR, EXAFS) and near-surface ( $\beta\text{-Co}^{\text{II+x}}\text{O}_x(\text{OH})_{2-x}$ ; see also XPS Fig. S16, ESI†) structure are different for Co–KOH.

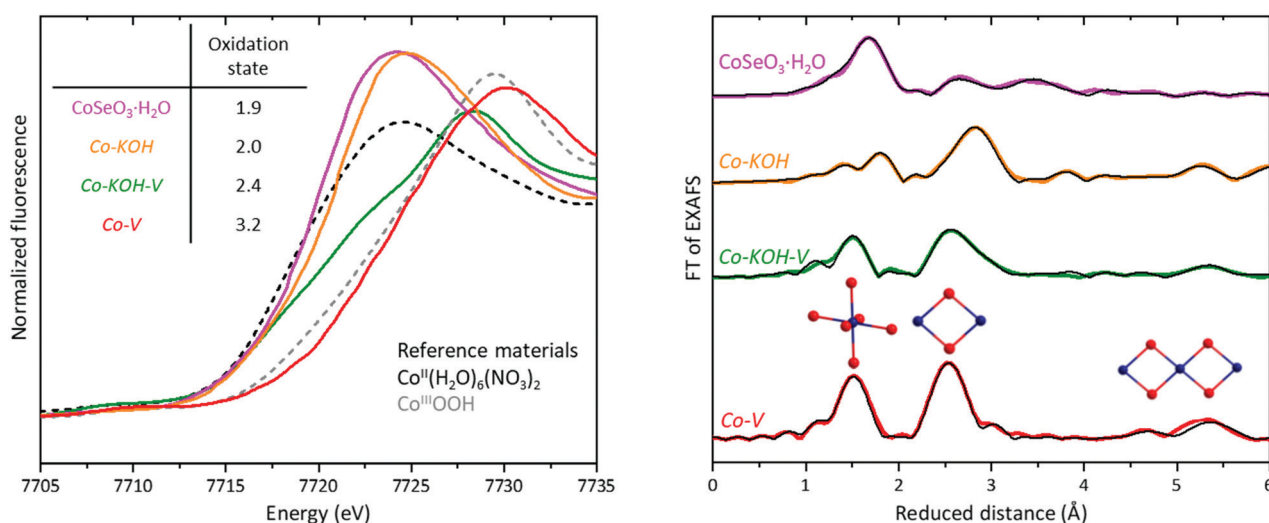

The  $E_g$  band of  $\text{CoOOH}$  is also present in the quasi *in situ* RR of Co–KOH–V together with the symmetric stretching vibration of Co–O ( $A_{1g}$ ) as a broad feature.<sup>73–76</sup> Additionally, a small shoulder at  $490\text{ cm}^{-1}$  indicates the presence of a minor phase similar to the one observed in the RR of Co–V. Fig. S28 (ESI†) shows the RR spectrum of Co–KOH–V measured after the sample was exposed to air at room temperature for 2 h. Signature bands of  $\text{Co}_3\text{O}_4$  appear after the air exposure, confirming the reported reversible transformation of  $\text{CoOOH}$  to  $\text{Co}_3\text{O}_4$ .<sup>69</sup> A similar behavior was observed for *ex situ* measurements of Co–V (see Fig. S28, ESI†).

For Co–V, the quasi *in situ* RR spectrum shows two bands, which we assigned to the Co–O–Co bending ( $474\text{ cm}^{-1}$ ) and the Co–O symmetric stretching ( $581\text{ cm}^{-1}$ ) vibrations<sup>48</sup> in analogy to both crystalline  $\text{LiCoO}_2$  ( $487$  and  $595\text{ cm}^{-1}$ ) and amorphous CoBi ( $503$  and  $607\text{ cm}^{-1}$ ) that both adopt similar LOH structures like Co–V.<sup>48</sup> The two bands of these compounds are shifted in the order  $\text{CoBi} > \text{LiCoO}_2 > \text{Co–V}$ . *In situ* measurements of the intercalation of water into  $\text{LiCoO}_2$  and *vice versa* revealed that the location of these peaks is a function of the spacings (lower wavenumbers indicates a larger spacing).<sup>77,78</sup> X-ray pair distribution function analysis disclosed a layer spacing of  $6.67\text{ \AA}$  for CoBi;<sup>47</sup> crystallographic data unveiled a spacing of  $7.01\text{ \AA}$  for  $\text{LiCoO}_2$ ;<sup>79</sup> HR-TEM investigations uncover a spacing of  $8.9\text{ \AA}$  for Co–V (see Fig. 7 and Fig. S25, ESI†). Hence, the RR shifts confirm the large layer spacing observed in the HR-TEM of Co–V. Further, Co–V has sharper Raman peaks than CoBi but significantly broader ones than  $\text{LiCoO}_2$  indicating that Co–V is

more ordered than amorphous CoBi but lacks the crystallinity of  $\text{LiCoO}_2$ .<sup>48</sup>

**X-ray absorption spectroscopy.** XANES provides insight into the average, bulk oxidation state of the metal ions. Fig. 10 shows the cobalt K-edge XANES spectra of the four samples  $\text{CoSeO}_3\cdot\text{H}_2\text{O}$ , Co–KOH, quasi *in situ* Co–KOH–V and quasi *in situ* Co–V as well as of a  $\text{Co}^{\text{II}}$  and  $\text{Co}^{\text{III}}$  reference compound. The table in Fig. 10 displays the obtained oxidation states for  $\text{CoSeO}_3\cdot\text{H}_2\text{O}$  powder, Co–KOH, Co–KOH–V, and Co–V (for more information see Fig. S29, ESI†). These values are consistent with the proposed structures of all materials. For Co–V, an *in situ* oxidation state above  $\text{Co}^{\text{III}}$  is consistent with proposed OER reaction mechanisms, where  $\text{Co}^{\text{IV}}$  ions are part of the catalytically active sites (see Discussion section). To gain more insights into the redox behavior of Co–V, three additional samples were measured: (i) Co–V freeze quenched below the  $\text{Co}^{\text{II/III}}$  redox transition at  $0.9\text{ V}_{\text{RHE}}$ , (ii) above the  $\text{Co}^{\text{II/III}}$  redox transition at  $1.27\text{ V}_{\text{RHE}}$ , and (iii) *ex situ* after catalysis (see Fig. S30, ESI†). The obtained oxidation states were 2.6, 3.0, and 3.0, respectively. This data is consistent with the assignment and quantification of the redox features from the CV (see Fig. 5(b) and Fig. S11, ESI†).

EXAFS analysis reveals detailed structural information about amorphous and crystalline materials. Simulating the Co K-edge EXAFS region provides radii ( $R$ ), the atomic nature, and population ( $N$ , EXAFS coordination number) of coordination spheres around cobalt. The accuracy decreases with the radii and increases with the atomic number of the scattering atoms. Fig. 10 shows the cobalt K-edge Fourier-transformed EXAFS spectra of the four samples  $\text{CoSeO}_3\cdot\text{H}_2\text{O}$ , Co–KOH, *in situ* Co–KOH–V, and *in situ* Co–V as well as the corresponding simulations. EXAFS tables and the original spectra can be found in Fig. S31 and Tables S1–S5 (ESI†).  $\text{CoSeO}_3\cdot\text{H}_2\text{O}$  powder and on FTO deposited films could be well simulated based on

**Fig. 10** Left: *In situ* XANES spectra collected at the cobalt K-edge of  $\text{CoSeO}_3\cdot\text{H}_2\text{O}$ , Co–KOH, Co–KOH–V, and Co–V as well as two reference compounds for  $\text{Co}^{\text{II}}$  and  $\text{Co}^{\text{III}}$ . Right: Fourier-transformed K-edge EXAFS spectra of  $\text{CoSeO}_3\cdot\text{H}_2\text{O}$ , Co–KOH, Co–KOH–V, and Co–V. The black lines are the simulated spectra. The internuclear distances obtained by the EXAFS simulations are around  $0.2\text{--}0.4\text{ \AA}$  larger than the indicated reduced distances. The structural motifs represent the connectivity of the atoms causing the peaks with oxygen in red and cobalt in blue.

the reported structures determined by XRD.<sup>54,56</sup> Co-KOH was successfully fitted based on the  $\beta$ -Co(OH)<sub>2</sub> structure ( $P\bar{3}m1$ ,  $a = 3.18$  Å and  $c = 4.65$  Å, JCPDS 30-443). For Co-KOH-V, two structural models were required to obtain a conclusive simulation:  $\beta$ -Co(OH)<sub>2</sub> and  $\beta$ -CoOOH ( $R\bar{3}m$ ,  $a = 2.85$  Å and  $c = 13.15$  Å, JCPDS 7-169). The fraction of the two phases was determined as 40%  $\beta$ -Co(OH)<sub>2</sub> and 60%  $\beta$ -COOH. This distribution is consistent with the XANES, IR, RR, and SAED results, which also reveal the coexistence of these two phases.

For X-ray amorphous Co-V, the Fourier transformed EXAFS spectrum shows four major peaks (Fig. 10). Fig. 8 left shows a structural model with the respective coordination spheres. The first peak is the Co-O distances (1.88 Å,  $N = 5.3$ ), as shown in the octahedra of Fig. 10. In the layered Co(OH<sub>x</sub>)<sub>2</sub> structure of Fig. 8, the octahedra are distorted, but all Co-O distances are equivalent (see Fig. 12(b) for bond lengths and angles calculated based on EXAFS data). Essentially the same distortion is present in crystalline CoOOH phases, leading to a contraction of the individual Co(OH<sub>x</sub>)<sub>2</sub> layers (the distance between two oxygen layers adjacent to the intermediate cobalt layer decreases see Fig. 8 right). The second peak is the first Co-Co coordination shell (2.83 Å,  $N = 5.0$ ). The third and fourth peaks are the second and third Co-Co coordination shells (4.92 Å with  $N = 2.5$ ; 5.65 Å with  $N = 2.7$ ). Depending on the arrangement of the edge-sharing octahedra, two different distances are possible. Additionally, one Co-O coordination shell (3.40 Å,  $N = 4.5$ ) with lower intensities was included in the EXAFS simulations, to facilitate high-quality simulation of the obtained spectrum (see Table S5, ESI† for simulation details).

The structural model in Fig. 8 was derived from the EXAFS and HR-TEM data. The white rings represent the EXAFS coordination shells. The figure includes another Co-O shell that was not included in the simulations due to its low intensity caused by the large radius and low atomic number of oxygen. The two Co-V samples freeze-quenched at 0.9 and 1.27 V<sub>RHE</sub> and the one measured *ex situ* could be fitted with the same structural model with minor variations (see Fig. S32 and Tables S6–S8, ESI†).

## Discussion

### The structure of Co-V, Co-KOH, and Co-KOH-V

We have shown that, starting from a single compound, CoSeO<sub>3</sub>·H<sub>2</sub>O, depending on  $V$  and pH (see Fig. 4), three distinct materials and among them two OER catalysts with substantially different activities and structural properties can be obtained. All three materials (Co-KOH, Co-KOH-V, and Co-V) no longer contain significant amounts of selenium and consist of layers formed by edge-sharing [CoO<sub>6</sub>] octahedra.

For Co-KOH, crystalline  $\beta$ -Co(OH)<sub>2</sub> with an average cobalt oxidation state of two and a layer spacing of 4.65 Å is obtained. On the surface, the sample is partly oxidized to  $\beta$ -CoOOH. The morphology at the nanometer and micrometer scale is also affected by the transformation; most of the initial chunks and needles of several micrometer are transformed into hexagonal nanoplates. Co-KOH-V contains two phases. One is crystalline

$\beta$ -CoOOH with a layer spacing of 4.38 Å and a cobalt oxidation state of three (see Fig. 12(a)). The other one is the same  $\beta$ -Co(OH)<sub>2</sub> as found in Co-KOH, but with a lower crystallinity. The ratio of the two phases is approximately 60%  $\beta$ -COOH to 40%  $\beta$ -Co(OH)<sub>2</sub>. The morphology is similar to that of Co-KOH, showing hexagonal nanoplates.

In contrast to Co-KOH and Co-KOH-V, Co-V is X-ray amorphous. IR, SAED, HR-TEM, RR and EXAFS investigations disclose that it is also comprised of layers formed by edge-sharing [CoO<sub>6</sub>] octahedra (see Fig. 8). The observed EXAFS distances reveal that the [CoO<sub>6</sub>] octahedra are distorted. The O-Co-O angles were calculated from the first Co-O (1.88 Å) and Co-Co (2.83 Å) distance to be around 80 and 100° (see Fig. 12(b)). This distortion leads to a contraction of the layers (see Fig. 8 right), which previously has been related to OER activity.<sup>80</sup> HR-TEM could resolve the single layers (domains) with a size of 1–10 nm. These domains mostly arrange in an unordered way. Thus, the material lacks a long-range order and is X-ray amorphous. In some parts of the sample, the domains are larger and stack in parallel. In these parts, a layer spacing of around 8.9 Å was unveiled by HR-TEM, suggesting a layer of tightly bound water molecules and ions (K<sup>+</sup>, Co<sup>II/III</sup>, OH<sup>-</sup>) between Co(OH<sub>x</sub>)<sub>2</sub> sheets, in analogy to layered manganese oxides of the birnessite type.<sup>81,82</sup> RR spectroscopy shifts confirm a large layer spacing. The cobalt oxidation state in the relaxed *post* catalytic state is three. ICP-OES discloses that Co-V contains one potassium per two cobalt atoms. Therefore, we conclude that the hydrogen of the Co-OH groups, directed into the interlayer space, is largely replaced by potassium. For Co-V, the formation of hexagonal nanoparticles as in Co-KOH-(V) could not be observed.

### Electrochemical analysis of Co-V and Co-KOH-V

The two systems, Co-V and Co-KOH-V, were comprehensively investigated concerning their electrocatalytic properties and suitability as OER catalysts. CV measurements reveal that the electrocatalytic activity of Co-V is around 15 times higher than that of Co-KOH-V at current densities below 10 mA cm<sup>-2</sup>. A CP stability test over almost seven days without activity loss revealed that the superior performance is not a temporary phenomenon of a metastable amorphous phase but an intrinsic difference between the two systems. The comparison with other cobalt, nickel, and iron oxides and (oxy)hydroxides tested under the same conditions discloses that the activity of Co-KOH-V is mediocre, whereas the activity of Co-V is exceptionally high. The approximately one magnitude higher charge transfer resistance of Co-KOH-V confirms this activity trend. Steady-state Tafel slopes unveil two linear regions with the same slope for both catalysts. The first slope is around 46 mV dec<sup>-1</sup> and the second around 86 mV dec<sup>-1</sup>. The presence of a second linear region implies a change in the reaction mechanism or surface coverage.<sup>9,83–85</sup> As both systems, Co-V and Co-KOH-V, have the same two Tafel slopes, they both should have the same kind of active sites.

The reaction mechanism for the OER in LOH cobalt catalysts is not comprehensively understood. However, there are two

Fig. 11 Two mechanisms for the OER on  $\text{CoO}_x\text{H}_y$  catalysts with different O–O bond formation steps: (a) nucleophilic attack of hydroxide and (b) intramolecular oxygen coupling.

prevailing pathways in the discussion of O–O bond formation by cobalt oxyhydroxides.<sup>39,62,86,87</sup> The two pathways are depicted in Fig. 11. Pathway (a) involves the nucleophilic attack of hydroxide on a single  $\text{Co}^{\text{IV}-\delta}\text{O}^{\text{II}+\delta}$  species, leading to O–O bond formation. Pathway (b) proceeds through the intramolecular oxygen coupling of two adjacent  $\text{Co}^{\text{IV}-\delta}\text{O}^{\text{II}+\delta}$  species, leading to a bridging peroxido intermediate. Interestingly, time-resolved IR spectroscopy suggests that both mechanisms occur simultaneously on an *in situ*-formed cobalt LOH at near-neutral pH.<sup>87</sup> An increased V will lead to more  $\text{Co}^{\text{IV}-\delta}\text{O}^{\text{II}+\delta}$  species. Therefore, this should favor the intramolecular oxygen coupling with two adjacent  $\text{Co}^{\text{IV}-\delta}\text{O}^{\text{II}+\delta}$  species. Both proposed reaction mechanisms are consistent with our observation of an average *in situ* bulk oxidation state of 3.2 of Co–V.

### A structural model explaining the different catalytic performances

Based on the aforementioned conclusions, a model explaining the activity differences can be proposed: Co–KOH–V has large

domains and a small layer spacing; thus, only cobalt sites on the near-surface of the crystalline domains contribute to the OER. Whereas, in Co–V, the domains are small and the interlayers spacing is large; thus, the electrolyte can penetrate it, resulting in a bulk active catalyst. The smaller domains also lead to more edge sites containing  $\mu_2$ -oxo bridged cobalt atoms, which were previously suggested to be the redox and catalytically active species (the percentage of cobalt edge sites in the model shown in Fig. 8 correlates with the ratio of  $\text{Co}^{\text{II/III}}$  redox active species to inactive species).<sup>62</sup> A model for each catalyst is shown in Fig. 12 together with molecular species in the absolute relative size.<sup>88</sup> The figure shows that the layer spacing of Co–V is large enough for  $\text{K}^+$ ,  $\text{OH}^-$ ,  $\text{H}_2\text{O}$ ,  $\text{O}_2$ , and  $(\text{SeO}_4)^{2-}$ .

Several arguments can be raised to support this model such as the different layer spacings and domain sizes, the same Tafel slopes, the large Co–V redox features, and the *in situ* oxidation states determined by XANES. Further, normalization of the catalytic activity by the amount of  $\text{Co}^{\text{II/III}}$  redox active sites reveals that the activity per site is the same at low current densities ( $<10 \text{ mA cm}^{-2}$ ). At higher current densities, this similarity changes, probably due to mass transfer limitations.<sup>89</sup> *In situ* conductivity measurements of related compounds and the redox peak analysis of our report implies that electron transport is not the limiting phenomena.<sup>65,66</sup> The large amount of potassium in Co–V and the weak OH stretching vibration show that the KOH electrolyte can penetrate the whole Co–V catalyst and deprotonate the Co–OH sites.

For iron nickel LOH, theoretical investigations relating the OER performance to the layer spacing exist.<sup>90</sup> For layer distances above 6.5 Å, the OER mechanism (similar to the one in Fig. 11(a)) in the interlayer space was found to be analogous to the one occurring at the surface. The largest layer distance investigated was 8.0 Å.<sup>90</sup> Thus, the spacing of 8.9 Å found for Co–V is probably large enough that the OER mechanism within the layer and on the surface are the same. A similar relationship

Fig. 12 (a) Structure and layer stacking of  $\beta\text{-CoOOH}$  ( $R\bar{3}m$ , JCPDS 7-169) as present in Co–KOH–V. (b) Structural motif of Co–V with distances obtained by EXAFS simulation and resulting bond angles. (c) Structural model of an area of Co–V with parallel domain stacking showing the layer distance in correct relation to interlayer  $\text{K}^+$ ,  $\text{H}_2\text{O}$ , and  $\text{HO}^-$ ; the arrangement of the interlayer species is only illustrative and strongly simplified. (d) Different species in correct relative size to (c) with their respective radii for a coordination number of 6 in brackets.<sup>87</sup> The radius of  $(\text{SeO}_4)^{2-}$  was determined from the crystal structure of  $\text{CoSeO}_4$  (JPCDS 53-0405) and a radius of 1.40 Å for  $\text{O}^{\text{II}}$ .

between layer spacing and bulk activity was proposed for manganese birnessite with different intercalated alkali metals.<sup>91</sup>

### Redox activity and *in situ* oxidation state of Co–V

Quasi *in situ* XANES measurements were performed before the Co<sup>II/III</sup> redox feature, in between the Co<sup>II/III</sup> and Co<sup>III/IV</sup> redox features, and during the OER. They revealed the average oxidation states of +2.6, +3.0, and +3.2, respectively (see Fig. S28, ESI†). These oxidation states are consistent with the quantification of the redox peaks and the assigned transitions. EXAFS analysis discloses that the catalyst structure is retained during these oxidation state changes, unveiling its high flexibility. Similar redox states could be observed for bulk active CoPi at neutral pH.<sup>49,92,93</sup> Further, CoPi also acquires a LOH structure but with smaller domains and a less ordered arrangement.<sup>48</sup> However, in CoPi investigated at pH 13–14, the catalytic activity is lower,<sup>94</sup> the Tafel slope higher,<sup>40</sup> and the Co<sup>II/III</sup> and Co<sup>III/IV</sup> CV redox features are not well separated compared to Co–V.<sup>95</sup> These results show again that small differences in the structure of LOH can strongly affect the electrocatalytic properties. For Co–KOH–V, XANES indicated an average oxidation state of Co<sup>2.4</sup>. This result does not mean that no Co<sup>IV</sup> is formed at the surface, but as the material is not bulk redox/OER active, the average oxidation state remains low.

In light of the molecular concept of the “oxo wall”, the Co<sup>IV</sup> in Co–V might be best described by the two resonance structures Co<sup>III</sup>–O<sup>–II</sup> and Co<sup>IV</sup>–O<sup>–I</sup> (in sum Co<sup>IV–δ</sup>–O<sup>–II+δ</sup>),<sup>96</sup> if they are viewed as localized charges, as molecular cobalt cubane models indicate.<sup>97</sup> Alternatively, the charge could be delocalized over a complete domain. Recently, it was revealed that charge delocalization is highly sensitive to small structural changes in amorphous cobalt LOHs.<sup>48</sup> Larger, ordered domains, short Co–O bonds, and small Co–O–Co angles lead to a Co(4p)–O(2p)–Co(3d) hybridization and charge delocalization within a domain like in CoBi.<sup>48</sup> CoPi with a domain size of 1.1 nm, Co–O bond length of 1.92 Å, and Co–O–Co angles of 94.8° does not show such a hybridization in resonant X-ray emission and resonant inelastic X-ray scattering. In CoBi with a domain size of 2.0 nm, Co–O bond length of 1.9 Å and Co–O–Co angles of 96.3°, the same spectroscopic methods clearly indicate such a hybridization. Co–V has a domain size of around 1–5 nm, Co–O bond length of 1.88 Å and Co–O–Co angles of around 100°. Therefore, the degree of Co(4p)–O(2p)–Co(3d) hybridization and electron delocalization is expected to be comparable to or larger than in CoBi. The strong structure sensitivity implies that possibly no general answer can be given on the question whether cobalt LOH materials during catalysis are better described with localized Co<sup>IV</sup> centers or delocalized Co<sup>III+δ</sup> oxidation states.

### Synthetic considerations and generalization of the structural model

Co–V is dramatically more active than Co–KOH–V, due to differences in domains size and stacking. Therefore, it is important to understand the synthetic aspects that lead to such structural arrangement. Recently, pseudo *in situ* HR-TEM investigations unveiled that amorphous CoS<sub>x</sub> transforms to crystalline

CoOOH through crystalline Co(OH)<sub>2</sub> as intermediate.<sup>32</sup> This transformation pathway is identical to the one of Co–KOH–V. For Co–V, the key synthetic step is the immediate application of an electrical potential. The current response shown in Fig. 5(a) reveals that almost all the (Se<sup>IV</sup>O<sub>3</sub>)<sup>2–</sup> units are oxidized to (Se<sup>VI</sup>O<sub>4</sub>)<sup>2–</sup> within the first 10 s. The starting material CoSeO<sub>3</sub>·H<sub>2</sub>O already has a layered structure with a layer spacing of 6.6 Å. [CoO<sub>6</sub>] octahedra are connected by [Se<sup>IV</sup>O<sub>3</sub>] units, which point into the interlayer space. The immediate oxidation of the [Se<sup>IV</sup>O<sub>3</sub>] units to larger tetrahedral (Se<sup>VI</sup>O<sub>4</sub>)<sup>2–</sup> must result in an increased layer distance due to steric repulsion. Further, all selenate left the structure after 1 h of electrocatalysis. Therefore, the interlayer space must be big enough to allow the diffusion of the selenate. A model with correct relative sizes of the proposed Co–V structure and a space filling model of selenate is shown in Fig. 12(c) and (d). It reveals that the layer spacing of 8.9 Å is just large enough for the selenate. Thus, the role of selenate can be best described as a nanotemplate. This consideration directly links the anion type and structure of the precatalyst to the layer spacing and structure of the LOH catalyst.

We think that another decisive aspect for the formation of an electrolyte-penetrable, porous phase is the large volume per cobalt atom in the precatalyst structure combined with the rapid transformation. In CoSeO<sub>3</sub>·H<sub>2</sub>O, the layers are comprised of [CoO<sub>6</sub>] octahedra, which are connected *via* four corners to another four [CoO<sub>6</sub>] units (Co–Co distance 4.1 Å, see Fig. 2 right). In comparison, the cobalt atoms are much closer to each other in layers of LOH phases, which are comprised of edge sharing [CoO<sub>6</sub>] units with six closest cobalt neighbors at 2.83 Å (see Fig. 8). Further, CoSeO<sub>3</sub>·H<sub>2</sub>O contains water and [SeO<sub>3</sub>] in its interlayer space already. Thus, to form a non-porous densely packed CoOOH phase without interlayer cations and water starting from CoSeO<sub>3</sub>·H<sub>2</sub>O, the volume of the material would have to shrink by 65%, based on the volume per cobalt atom of the unit cells of CoSeO<sub>3</sub>·H<sub>2</sub>O (89.5 Å<sup>3</sup> per Co) compared to β-CoOOH (30.8 Å<sup>3</sup> per cobalt). Due to the rapid transformation and the dramatical volume difference, the thermodynamically favored dense β-CoOOH phase is avoided and instead a sub-nanometer porous structure with incorporated electrolyte and a volume closer to the one of CoSeO<sub>3</sub>·H<sub>2</sub>O is formed.

There is an ongoing debate whether NiFeO<sub>x</sub>H<sub>y</sub>, the currently most promising alkaline OER catalysts, is bulk or surface active.<sup>98–100</sup> Recently, Chorkendorff and coworkers provided evidence that, for NiFeO<sub>x</sub>H<sub>y</sub> nanoparticles, the catalytic activity is limited to the near-surface region.<sup>100</sup> However, previous investigations found that the bulk of Ni(Fe)O<sub>x</sub>H<sub>y</sub> is redox active (especially for pure nickel) and could also participate in the OER.<sup>90,99,101,102</sup> Further, theoretical calculations revealed similar OER reaction intermediates for surface (001) and bulk sites in NiFeOOH LOH with a layer spacing of 6.5 Å to 8.0 Å, indicating that bulk activity is possible.<sup>90</sup> Our report proves that both LOH of cobalt that are bulk active and such that are only near-surface-active exist. Applying this knowledge to NiFeO<sub>x</sub>H<sub>y</sub>, allows the observed discrepancies to be explained. In Chorkendorff's report, the NiFeO<sub>x</sub>H<sub>y</sub> was formed *in situ* out of metallic FeNi nanoparticles. Small layer spacing (Fe doped β-NiOOH)

probably result from the high density of the metallic nanoparticles (the precatalyst) and the absence of an anion that could leach.<sup>103</sup> Thus, it is expected that such NiFeO<sub>x</sub>H<sub>y</sub> are only near-surface-active, like Co-KOH-V. However, other synthetic routes lead to materials with a larger layer spacing and small domain sizes. Therefore, they are electrolyte-penetrable and bulk-active, like Co-V. This hypothesis is further supported by recent investigations on the layer spacing and stability of crystalline NiFeO<sub>x</sub>H<sub>y</sub>.<sup>89</sup> These investigations revealed that slow hydroxide diffusion between the layers ( $d = 7.5 \text{ \AA}$ ) leads to an acidification of the interlayer space, due to the OER occurring there, and finally to a dissolution of nickel and iron.

## Conclusions

As predicted from a thermodynamic point of view, most materials transform during OER conditions and form LOH. To explore this transformation, we have investigated CoSeO<sub>3</sub>·H<sub>2</sub>O as an OER precatalyst and could obtain two different OER catalysts (Co-V and Co-KOH-V) by varying the pH and potential, clearly answering research question (a) from the introduction. The OER performance of Co-V is 15 times higher than that of Co-KOH-V, but Tafel analyses suggest that both catalyst materials share the same kind of active site. We derived a model that explains these findings: Co-V is bulk-active and Co-KOH-V only active in its near-surface region. Further, Co-V contains more  $\mu_2$ -oxo bridged cobalt edge sites, due to the smaller domains. In respect to research question (b), this model was correlated with the structures of the two catalysts. Both catalysts have the same short-range structure, layers of edge-sharing [CoO<sub>6</sub>] octahedra, but they vary strongly in the arrangement of these layers. In Co-KOH-V, the layers are large and stack in parallel with a layer spacing of 4.38 Å, forming crystalline  $\beta$ -CoOOH, which does not leave room for penetration of (substrate) water molecules. Conversely, in Co-V, the layers are only around 1–10 nm in size and stack in an unordered way, forming an X-ray amorphous phase. Still some of the layers stack in parallel, and in these cases, HR-TEM could visualize a layer spacing of 8.9 Å, which suggest the presence of intercalated (substrate) water, hydroxide and potassium. The structure of Co-V permits electrolyte penetration, enabling catalytic activity of the whole material. In respect to research questions (c) and (d), we explained the unique structure of Co-V by a strong contraction of the precatalyst cobalt layers and a nanotemplate effect of the rapidly forming and subsequently leaching of (Se<sup>VI</sup>O<sub>4</sub>)<sup>2-</sup>.

This work shows that LOH of the same TM can have starkly different catalytic properties due to the structural differences revealed by our study. The models derived from the detailed characterization performed in this work can help to explain the apparently contradicting observation of in some cases near-surface active and in other cases bulk active iron/cobalt/nickel LOH catalysts. Another significant message conveyed herein is that, even though most materials will transform into LOH, their structures can differ pronouncedly and some of the precursor-derived OER catalyst materials are more active than catalysts

obtained by straightforward synthesis of LOH. Therefore, we believe that the investigation of under OER-conditions metastable chalcogenides, pnictides, carbides, borides, phosphates, phosphites, borates, and intermetallic TM materials is of high interest, even though these anions may no longer be present in the final catalyst material.

## Acknowledgements

The authors are indebted to Dr Vitaly Gutkin for XPS, Dr Stefan Behrens, Eva M. Heppke and Ina Speckman for pXRD. We thank the Helmholtz Zentrum Berlin (HZB) for providing access to the BESSY synchrotron (XAS experiment at KMC-3) and Drs Ivo Zizak and Götz Schuck as well as further HZB staff for experimental support. We are grateful to the Einstein Center of Catalysis (EC2) for financial support. This project was also funded by the Deutsche Forschungsgemeinschaft (DFG, German Research Foundation) under Germany's Excellence Strategy – EXC 2008 – 390540038 – UniSysCat; the Bundesministerium für Bildung und Forschung (BMBF) provided financial support to the *Operando*-XAS project.
