## Abstract

The Euphrates-Tigris catchment area is one of the major drainage basins in the Middle East but climate change, overuse of waters and subsequent salinization has brought this region to the brink of ecological devastation. The aim of this study was to investigate the biodiversity of epiphytic diatoms in Iraq, for the first time using a combination of morphological and metabarcoding methods. 47 samples were collected at six sampling sites along the Rivers Tigris and Euphrates in northern Basra, Southern Iraq, during the summer of 2019 (dry season) and winter of 2020 (rainy season). The composition of the epiphytic diatoms in each sample was compared with both methods. The microscopic-morphological analysis of the environmental samples resulted in the identification of 284 infrageneric taxa in 59 genera. For the metabarcoding analysis the V4 region of the 18S marker gene was used and resulted in 1454 ASVs (Amplicon sequence variants) comprising 54 genera and 108 species with several ASVs belonging to the same taxa. The non-metric multidimensional scaling (NMDS) plots for morphology showed a clear seasonal effect in the diatom community composition, while the NMDS plots for 18SV4 analyses did not show a seasonal effect in community composition for the same samples. The incomplete taxonomic reference database for the studied sites turned out to be the major limitation of the molecular approach. Nevertheless, the combination of morphological and molecular methods increased the detection and identification of the diatom assemblages and laid the foundation for understanding their biodiversity in this region.

**Key words:** 18SV4, DNA metabarcoding, epiphytic diatoms, Euphrates-Tigris River, microscopical analysis

## Introduction

The Euphrates-Tigris area is one of the major drainage basins in the Middle East (Hassan et al. 2010). Overexploitation has pushed the water system to its ecological limits. Iraqi waterbodies suffer from salinization (Al-Handal et al. 2014) due to water losses caused by factors such as water policies during the Iraq wars, the construction of dams upstream and the impact of climate change on

the region. The country experiences minimal rainfall, particularly in the central and southern regions, leading to arid conditions (Hashim et al. 2022).

Diatoms (Bacillariophyta) are a diverse group of microalgae that play a significant role in aquatic ecosystems, serving as primary producers and contributing to the understanding of these ecosystems' functioning (Rimet et al. 2018). Several local and regional monitoring programs and networks use diatom-based indices to monitor biotic integrity and water quality (Tapolczai et al. 2024). They are globally the most commonly used bioindicators for water quality (Round et al. 1990; Visco et al. 2015), due to their unique ability to reflect ecosystem conditions (Battarbee et al. 2001; Kang et al. 2021).

Epiphytic diatoms live on the surfaces of plants, particularly submerged macrophytes. Different species of diatoms are often found on different types of macrophytes, even within the same habitat. These epiphytic communities are particularly interesting because they are attached to living plants and can interact with their hosts in various ways, potentially affecting their own community structure (Al-Handal et al. 2014). Handling of diatoms in terms of sampling, processing and storage can be managed with minor effort. Due to their silicified cell walls diatoms have the ability to survive in sediments of various composition for a long time. This quality predestines them to be universally used to examine water quality including continual changes in lakes. (Liu et al. 2017; Kang et al. 2021).

Accurate taxonomic identification of diatoms is essential for the sound evaluation of their diversity. However, diatom identification based on counting and identifying their valves using mostly light microscopy requires highly specialized taxonomic skills (Bíró et al. 2022; Stuart et al. 2024) and may lead to discrepancies in the findings depending on the researcher (Kang et al. 2021). In addition, one of the important factors that can hinder the accurate identification of classical species in diatoms is the presence of cryptic diversity. (Hadi et al. 2016; Nistal-García et al. 2021). Among the studies that have focused on the hidden diversity in diatoms are Trobajo et al. (2010); Rovira et al. (2015); Rivera et al. (2018); Pinseel et al. (2019). Furthermore, in regions where literature on the local diatom flora is not available, researchers often rely on European floras, which may force identifications into the existing taxonomic concepts, potentially overlooking local variation or unique species.

To optimize diatom identification, DNA metabarcoding is increasingly used because it is generally less time-consuming and may be more accurate than morphological identification. This method enables the concurrent identification of numerous species from environmental samples (Ruppert et al. 2019; Kang et al. 2021).

This method has been used to investigate freshwater diatom biodiversity (Mora et al. 2019) and has also been leveraged for the evaluation of water quality with a focus on benthic diatoms (Vasselon et al. 2017; Baillet et al. 2019; Mortágua et al. 2019; Kelly et al. 2020; Pérez-Burillo et al. 2020). It has also been applied to some extent to marine environments (Malviya et al. 2016; Piredda et al. 2018; Schimani et al. 2023). Even though the DNA barcoding reference database needs to grow and expand, metabarcoding has proven to be an efficient tool for surveying diatom communities in comparison to morphological analyses (Zimmermann et al. 2015; Keck et al. 2018; Rivera et al. 2018).

While metabarcoding has seen widespread adoption globally over the past decade for diatom analysis (Burki et al. 2021; Almandoz et al. 2024), there is a notable absence of such studies in Iraq. Given that our current understanding of diatoms largely relies on microscopic-morphological studies, it seemed opportune

to combine both approaches to enrich our comprehension of the epiphytic diatom community composition in this area. By integrating metabarcoding and traditional microscopic analysis, a more comprehensive and detailed insight into the diversity and dynamics of diatom populations within the region can be obtained.

In this study, the aim was to identify the biodiversity of epiphytic diatoms using metabarcoding of diatom 18SV4 DNA and classical methods (light and scanning electron microscopy), followed by a comparison of differences in diatom species and abundance inventories obtained by both methods. This analysis was conducted on a set of 47 samples collected from two different water bodies in Iraq, namely the River Tigris and River Euphrates.

## Materials and methods

### Study area and sample collection

Epiphytic diatoms were sampled from freshwaters during the summer of 2019 and winter of 2020, encompassing 47 samples from six sites across two water bodies in Iraq: River Tigris in the city of Al-Qurnah, and River Euphrates in the city of Al-Midaina (Fig. 1). Due to the absence of stones as habitats at either of the sampling stations, samples were collected separately from 11 different taxa of macrophytes, including *Phragmites australis*, *Typha domingensis*, *Ceratophyllum demersum*, *Myriophyllum spicatum*, *Potamogeton crispus*, *Potamogeton perfoliatus*, *Potamogeton* sp., *Cladophora glomerata*, *Cladophora* spp., *Najas minor* and *Aster tripolium* (Table 1). At least five stems and branches in good condition of a macrophyte or macroalga were put into a plastic bag, and then shaken vigorously with distilled water to dislodge attached diatoms. The resulting suspension was poured into a plastic container and preserved with 70% alcohol for transportation to the laboratory at the Botanic Garden and Botanical Museum (BGBM), Freie Universität Berlin. Each sample was divided into two portions for subsequent analysis, including 1) the morphological identification of the diatom community, and 2) a community analysis conducted via DNA metabarcoding.

### Physical and chemical parameters

Water samples for physical-chemical parameters analyses were taken at the same sites where diatom sampling was carried out (Table 2). These included air and water temperature (°C), pH, conductivity ( $\mu\text{S}\cdot\text{cm}^{-1}$ ), dissolved oxygen ( $\text{mg}\cdot\text{l}^{-1}$ ), water transparency (cm), turbidity (NTU), and total alkalinity ( $\text{mg}\cdot\text{l}^{-1}$ ), using different instruments. Nitrate ( $\text{mg}\cdot\text{l}^{-1}$ ), phosphate ( $\text{mg}\cdot\text{l}^{-1}$ ) and silicate ( $\text{mg}\cdot\text{l}^{-1}$ ) were measured according to Strickland and Parsons (1972), Lind (1979) and APHA (1999, 2005).

### Microscopical analysis

Environmental samples underwent treatment with 35% hydrogen peroxide at room temperature to facilitate the oxidation of organic materials. Following this, the samples were thoroughly washed with distilled water, employing the method outlined by Mora et al. (2019). The cleaned frustules and valves were air-dried on coverslips and mounted on microscopic slides using the high refractive index medium Naphrax®.

Figure 1. Area of study: Location of the six sampling sites in the Rivers Tigris and Euphrates indicated by red dots. The numbers next to the red dots refer to the name of the sampling site in Table 1.

To investigate the composition of epiphytic diatoms, each environmental sample was examined using light microscopy (LM). The Zeiss Axioplan microscope equipped with differential interference contrast (DIC) was employed, using a Zeiss 100× Plan Apochromat objective with the AXIOCAM MRc camera. All samples were measured using the AxioVision software.

**Table 1.** Sampling sites with information on the sampling station, voucher, georeference, substrates, taxon richness and Shannon diversity index. The samples were collected by Maitham Al-Shaheen. Legend: T = Tigris River, E = Euphrates River, S = summer, W = winter, LM = microscopic morphology, M = metabarcoding. Substrates: *Ph. australis* (Cav.) Steud., *T. domingensis* Pers., *C. demersum* L., *M. spicatum* L., *P. crispus* L., *P. perfoliatus* L., *Potamogeton* sp., *C. glomerata* (L.) Kütz, *Cladophora* spp., *N. minor* All. and *A. tripolium* L.

To document the presence and abundance of each diatom taxon across all sampling sites, a minimum of 400 valves were counted in each sample, and subsequently, the relative abundance of each taxon was calculated. When more details were needed, aliquots of cleaned sample material for scanning electron microscopy observations were mounted on stubs and observed under a Hitachi FE 8010 scanning electron microscope (SEM) operated at 1.0 kV. Samples, slides and pictures are deposited in a database at the Diatom Collection of the Botanic Garden and Botanical Museum Berlin, Freie Universität Berlin.

### Morphological analysis

The morphological information by both LM and scanning electron microscopy (SEM) was used to identify the diatoms to the lowest taxonomical rank possible (Table 3). Whenever possible, identification literature from the region was consulted, but often European literature was used due to the lack of specific identification literature for the region. Morphological identification followed predominantly Al-Handal and Al-Shaheen (2019), Lange-Bertalot et al. (2017), Krammer (2002), Krammer and Lange-Bertalot (1986, 1991), Witkowski et al. (2000), and Reichardt (2018). For nomenclatural authors and references for identification of each name, see Table 3. Species marked as new to Iraq are species not included in Maulood et al. (2013) and Al-Handal and Al-Shaheen (2019) as well as missing in the Distribution section in AlgaeBase (Guiry and Guiry 2024).

### Metabarcoding analyses

#### DNA extraction and PCR amplification

Samples were centrifuged at 11.000 rpm for 5 minutes. The supernatant was discarded and the DNA extracted from the pellet following the standard protocol proposed with the NucleoSpin® Soil Kit of Macherey and Nagel (MN-Soil). DNA samples were stored at -20 °C for future use and finally deposited in the Berlin collection of the DNA bank network (Gemeinholzer et al. 2011).

The V4 region of the 18S rRNA gene for 47 samples was amplified by PCR using primers DIV4 for: 5'-GCGGTAATTCCAGCTCCAATAG-3' and DIV4rev3: 5' - CTCTGACAATGGAATACGAATA-3', following the protocols and primers outlined by Visco et al. (2015), with modifications for 300-bp paired-end sequencing on the Illumina MiSeq, as adapted from Zimmermann et al. (2011). PCR amplifications were performed in duplicate per sample, using two different polymerases, each in a total volume of 25  $\mu$ L, to increase amplification success across all samples. This approach was necessary as some samples did not amplify successfully with the first polymerase but yielded successful results with the second. The PCR mix with the first polymerase contained 0.5  $\mu$ L dNTP mix (25 mM each dNTP), 0.25  $\mu$ L BSA (10 mg/mL), 0.25  $\mu$ L DMSO, 1  $\mu$ L of each forward and reverse primers (10 pm/ $\mu$ L), 0.4  $\mu$ L of Herculase II Fusion DNA Polymerase (Agilent Technologies Inc., Santa Clara, California, USA), 5  $\mu$ L Herculase II reaction buffer, 1  $\mu$ L of template DNA (20 ng/ $\mu$ L) and 15.6  $\mu$ L of HPLC grade water. The PCR regime included an initial denaturation at 94 °C (2 minutes) followed by 35 cycles consisting of denaturation at 94 °C (45 seconds), annealing at 52 °C (45 seconds), elongation at 72 °C (1 minute) and a final elongation at 72 °C (10 minutes).

The PCR mix with the second polymerase contained each in a total volume of 25  $\mu$ L: 2  $\mu$ L dNTP (Takara), 1.25  $\mu$ L BSA (10 mg/mL), 1.25  $\mu$ L of each forward and reverse primers (10 pm/ $\mu$ L), 0.15  $\mu$ L of Takara DNA Polymerase, 2.5  $\mu$ L buffer (10 $\times$ ), 1  $\mu$ L of template DNA (20 ng/ $\mu$ L) and 16.1  $\mu$ L of HPLC grade water. The PCR regime included an initial denaturation at 95 °C (2 minutes) followed by 33 cycles consisting of denaturation at 95 °C (1 minute), annealing at 54 °C (1 minute), elongation at 72 °C (1 minute) and a final elongation at 72 °C (5 minutes).

Size and quantification of DNA fragments was measured with the Fragment Analyzer™ (dsDNA 930 Reagent Kit, 75 bp-20000 bp) system was followed for quality control of PCR products. The DNA fragment was considered valid when the size was between 390 and 450 bps and the concentration was greater than 1 ng/ $\mu$ L

Aliquot of 25  $\mu$ L of the amplicons were purified using HighPrep PCR paramagnetic beads (Magbio Genomics). A second PCR run, the indexing PCR, was conducted on the purified samples to ligate a unique combination of tags to the 5' end of the primer. Indexing PCR reactions of 25  $\mu$ L were conducted as follows: 0.25 dNTP mix, 1  $\mu$ L DMSO, 0.625  $\mu$ L of each primer, 0.25  $\mu$ L of Herculase, 5  $\mu$ L Herculase II reaction buffer, 10  $\mu$ L of template DNA and 7.25  $\mu$ L of HPLC grade water. The indexing PCR regime started with denaturation at 95 °C (2 minutes), then 8 cycles consisting of denaturation at 95 °C (20 seconds), annealing at 52 °C (30 seconds), elongation at 72 °C (30 seconds) and a final elongation at 72 °C (3 minutes). PCR fragments' size concentrations were checked by Fragment Analyzer (1 $\times$  TE Dilution Buffer). Products were purified using HighPrep PCR paramagnetic beads and quantified using Quant (2.0)-iT PicoGreen dsDNA Assay Kit (Invitrogen, Carlsbad, California, USA) and adjusted to a concentration of 20 ng/ $\mu$ L. Library preparation was performed using MiSeq Reagent Kit V3 (300 bp paired-end reads) (Illumina, San Diego, California, USA). MiSeq sequencing with 600 cycles was conducted at the Berlin Center for Genomics in Biodiversity Research (BeGenDiv) of the Berlin Brandenburg Institute of Advanced Biodiversity Research (BBI-B). Raw demultiplexed reads were deposited at GenBanks Sequence Read Archive and are available under project number PRJNA1148423.

**Table 3.** List of all species observed in light microscopy (LM) with author(s) and reference(s) for identification. (r) behind the taxon name indicates that it was a rare species just observed in a thorough scan of the slide. Species new to the flora of Iraq are marked by an asterisk. cf. (confer) before the epithet indicates taxonomic uncertainty, aff. (affinis): indicates that the specimen is thought to be closely similar to the specified species but is not confirmed as that species. and 'sp.' (species) was used when the taxon showed no similarity to any known species after thorough literature review, L = valve length [µm], W = valve width [µm], S = stria number in 10 µm, F = fibulae in 10 µm, D = diameter. TS = Tigris summer, TW = Tigris winter, ES = Euphrates summer, EW = Euphrates winter.

## Bioinformatics analysis

Samples have been demultiplexed and split into individual per-sample Fastq files, one corresponding to the forward reads (R1) and one to the reverse reads (R2). Then we conducted bioinformatic analyses on them to generate the Amplicon Sequence Variants (ASVs) that constituted the fundamental units on which further examinations were carried out. The DIV4for and DIV4rev primers from all the demultiplexed MiSeq reads were removed by cutadapt (Martin, 2011). ASVs were generated using the R package DADA2 (Callahan et al. 2016) after processing the resulting R1 and R2 reads together. Where the R1 and R2 reads were truncated at R1 to 220 bp and at R2 to 170 nucleotides, based on their quality profiles (median quality score < 30), and those reads with ambiguities or showing an expected error (maxEE) higher than 2 were removed. The DADA2 denoising algorithm was then applied to determine an error rates model in order to infer amplicon sequence variants (ASVs). Finally, ASVs detected as chimeras were discarded using the DADA2 function "removeBimeraDenovo".

Taxonomic assignment was performed using an own established reference library comprising the Diat.barcode library (Rimet et al. 2019) and the reference library of the Diatom research group of the Botanic Garden Berlin (5768 taxa for 18SV4). Relative read abundances of taxa were then calculated and used in subsequent analyses.

Following the bioinformatic analyses conducted with DADA2, the R package metabar was employed to detect and identify artefactual sequences, such as contaminants and tag-jumps (Zinger et al. 2021). The dataset underwent a thorough examination to identify dysfunctional PCRs based on PCR replicates similarities. Subsequently, the reads from replicates were aggregated.

## Data analysis

For assessing the effectiveness of the two methods in identifying taxa, the percentages of species and genera recorded molecularly and morphologically were calculated (relative abundances  $\geq 1\%$ ). Data processing, visualizations and statistical analysis were performed in R version 4.2.0. Alpha Diversity Indices, including taxa richness and the Shannon Diversity Index, were computed using the vegan 2.6 R package (Oksanen et al. 2022). Variations in community structure between samples collected from the Euphrates and Tigris Rivers during summer 2019 and winter 2020 were assessed using both metabarcoding and morphology data. The Bray-Curtis Dissimilarity Measure, implemented through phyloseq, was employed to quantify dissimilarities (to study the pattern of diatom assemblages), which were then visualized using Non-metric Multidimensional Scaling (NMDS) ordination.

Permutational multivariate analysis of variance (PERMANOVA) was used to evaluate the statistically significant differences in diatom community composition regarding location and season for the DNA metabarcoding and the LM dataset. For the PERMANOVA analyses the R package vegan was used.

Venn diagrams with Eulerr (Larsson 2021) were used to compare the number of species present in the summer and winter for both rivers as well as between the two rivers, based on DNA metabarcoding and the LM dataset. Barplot diagrams at the genus level were generated for both metabarcoding and morphology data using the R package phyloseq (McMurdie and Holmes 2013).

## Results

### Morphological analysis

A total of 181 diatom species were identified (relative abundances  $\geq 1\%$ ) (Figs 2–11). The additional 103 taxa were observed by scanning the whole slides looking for rare taxa, bringing the total diversity to 284 taxa belonging to 59 genera (Table 3). Notably, 46 species are recorded for the first time in the region and 62 others could not be identified to species level and are possibly new to science, as was the case with *Prestauroneis furatensis* H.Mohamad & N.Abarca, which was identified and described from the epiphytic community of the River Euphrates (Mohamad et al. in press).

The most common taxa (relative abundances  $\geq 1\%$ ) across Tigris samples were in decreasing order: *Navicula recens* (33.3%), *Cocconeis placentula* complex (23.9%) and *Navicula rostellata* (15.4%). Across Euphrates samples the most abundant taxa were: *Cocconeis placentula* complex (81%), *Achnanthyidium minutissimum* complex (62.1%) and *Encyonopsis cf. microcephala* (60.7%).

Table 2 presents a list of the physical and chemical composition of the water obtained from the sampling sites. The Euphrates generally exhibited higher values for conductivity, water temperature, silica, and transparency, while the Tigris had higher values for alkalinity, turbidity and nitrate.

### Metabarcoding analysis

The Illumina MiSeq sequencing run generated 6,118,319 reads for the 18SV4 marker from 43 samples (Sample 10 at station E1 in summer, Samples 36 and 40 at station E2 in winter and Sample 24 at station T2 in winter were unsuccessful with PCR). After processing the reads through the DADA2 pipeline and improvement of the dataset by metbaR 5,461,214 reads remained belonging to 2,953 amplicon sequence variants (ASVs).

The total amount of reads was 5,461,214 with 1,454 (49.2%) of all ASVs classified as Bacillariophyta. The remaining were identified as 383 (12.9%) Chlorophyta, 36 (1.2) Ochrophyta, 2 (0.07%) Heterokontophyta and 1078 (36.5%) NA. Here again, the majority of the non-diatom reads were assigned to Chlorophyta. From 1,454 ASVs 408 could be assigned to a species in the reference database, whereby several ASVs were assigned to the same species (108). 959 ASVs were assigned to the genus level, whereby several ASVs were assigned to the same genus. The ASVs with the most reads, in decreasing order, belong to: *Navicula directa*, *Cocconeis placentula* complex, NA (Fragilariophyceae) and *Nitzschia palea*. The maximum number of ASVs per sample was 218 (in sample E 35) and the minimum 14 (in sample E 17).

### Comparison of taxa detected by DNA metabarcoding and morphology

In most cases, metabarcoding analysis recovered more taxa than the morphological analysis. The metabarcoding analysis resulted in the identification of 1,454 ASVs, including 408 species with several ASVs belonging to the same taxa (108). Many species had no record in reference databases. Morphological analysis of environmental samples resulted in the identification of 284 taxa. At the genus level, 59 genera were recovered by morphology, whereas 54 genera were identified by metabarcoding analysis.

In total, 38 genera were retrieved in both datasets, with 21 genera identified only by morphological identification and 16 identified only by metabarcoding (Fig. 12).

The following genera were present only in the morphological analysis: *Amphipleura*, *Aulacoseira*, *Berkeleya*, *Caloneis*, *Craticula*, *Cyclostephanos*, *Envekadea*, *Fallacia*, *Hantzschia*, *Hippodonta*, *Luticola*, *Navicymbula*, *Parlibellus*, *Prestauroneis*, *Pseudofallacia*, *Scoliopleura*, *Sellaphora*, *Stauroneis*, *Synedropsis*, *Tabularia* and *Thalassiosira*.

While the genera found only in metabarcoding were: *Campylodiscus*, *Chaetoceros*, *Conticribra*, *Coscinodiscus*, *Cylindrotheca*, *Cymatopleura*, *Cymbopleura*, *Discostella*, *Eunotia*, *Fistulifera*, *Placoneis*, *Planothidium*, *Pseudostaurosira*, *Skeletonema*, *Staurosira* and *Tabellaria*.

### Comparison of relative abundances

A comparison of the relative abundance of the most abundant taxa revealed differences between the two methods (Figs 14, 15). The taxa with the highest relative abundance of reads were: *Navicula directa*, *Cocconeis placentula* complex, NA (Fragilariophyceae), *Nitzschia palea*, and *Gomphonella olivacea* ( $\equiv$  *Gomphonema olivaceum*). In terms of morphology, *Cocconeis placentula*

### Community analysis

According to the Shannon diversity index in the metabarcoding analysis (Table 1), the largest diatom diversity was found in winter in the River Euphrates at station E3 in sample 46, while the lowest values were recorded in summer in the River Euphrates E3 in sample 17. In the morphological analysis, the largest diatom diversity was found in summer in the River Euphrates at station E1 in sample 11, while the lowest values were recorded in winter in the River Euphrates E3 in sample 47. In general, the Shannon diversity indices were mostly higher in the metabarcoding analyses than in the morphological analyses.

Average taxa richness was also mostly higher in the metabarcoding than in the morphological analyses. In the metabarcoding analysis station W.E1.34 recorded the highest number of species (345), and station W.E3.43 the lowest number of species (5). In the morphological analysis, station S.E1.11 recorded the highest number of species (43), and station W.E3.47 the lowest number of species (11). Both approaches agreed that a low taxa richness was found in station E3 in Euphrates River and the highest richness in E1 in the same river.

For the samples collected from the Rivers Tigris and Euphrates the non-metric multidimensional scaling (NMDS) plots for morphology show a clear seasonal effect in community composition such as summer (= dry season) and winter (= rainy season) (Fig. 13, stress = 0.1). PERMANOVA confirmed a statistically significant differences in the community composition between the two seasons and the two rivers ( $F = 2.61$ ,  $p = 0.001$ ). This is in contrast to the NMDS plots for the 18SV4 analyses, where no clear seasonal effects in community composition for these samples were noted.

## Discussion

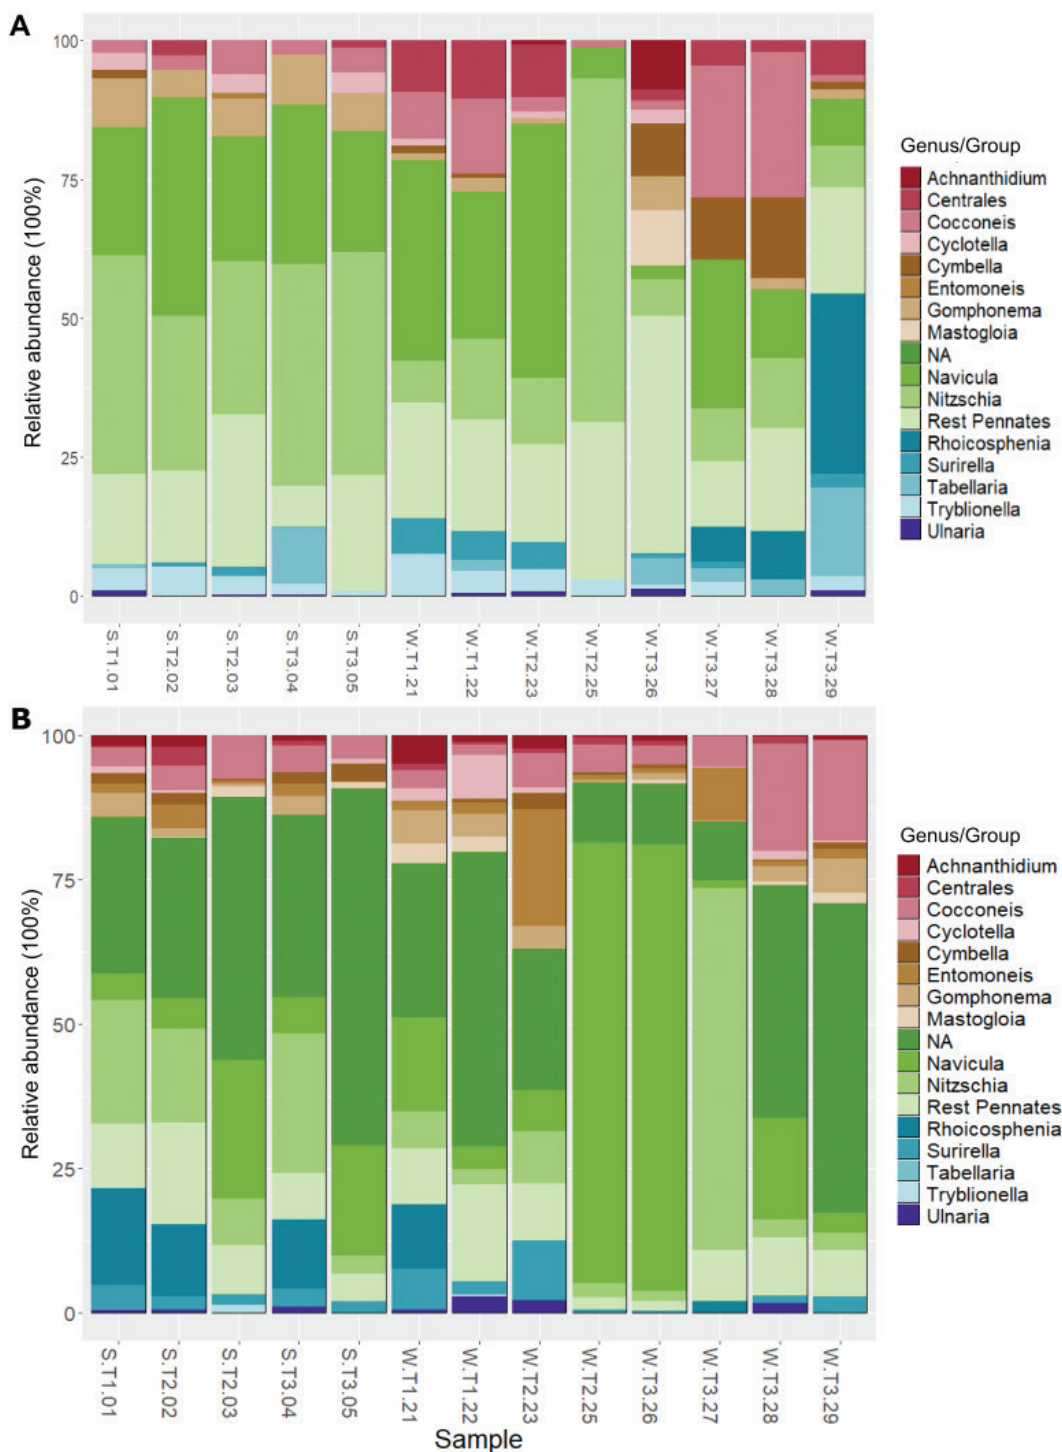

### Species composition by microscopy analysis

This study focused on epiphytic diatom taxa in the Euphrates-Tigris rivers, which are relatively shallow containing sediments covered by submerged macrophytes (Al-Handal et al. 2016), but no stones as habitats at the

**Figure 13.** Non-metric Multidimensional Scaling (NMDS) multivariate clustering of epiphytic diatom communities based on the variables of season and sampling sites. Stress: 0.1. Observing a clear distinction line between the Rivers Tigris (T) and Euphrates (E), with the dashed line indicating the separation between summer (S) and winter (W). A 18 SV4 marker gene, B Morphology.

sampling stations. The results of the diatom analyses revealed a diverse epiphytic diatom community. With 284 taxa identified, the species richness observed in this study was notably higher than that reported in previous studies: Al-Shaheen and Al-Handal (2017) identified 193 taxa belonging to 70 genera; Al-Handal et al. (2014) found 74 species of epiphytic diatoms belonging to 38 genera, and Al-Handal and Abdullah (2010) recorded 116 taxa representing 49 genera. Such comparisons are challenging due to various factors, including the quantity of samples analyzed, in which season of the year they were taken, which substrates were studied and the taxonomic depth applied to the diatom analysis (Mora et al. 2017). The higher diversity observed in

**Figure 14.** Relative abundance (%) of diatom genera across all sample locations for River Tigris. **A** Morphology. **B** 18SV4 marker gene. S: summer, W: winter.

our study can be attributed to the meticulous examination of samples using both microscopical instruments, LM and SEM, leading to the differentiation of several micromorphologically distinct taxa instead of grouping them into taxon complexes; although in some cases such as *Cocconeis placentula* and *Achnantheidium minutissimum* (for authors of species please consult Table 3) we had to use the term complex since currently data are missing for an internal differentiation.

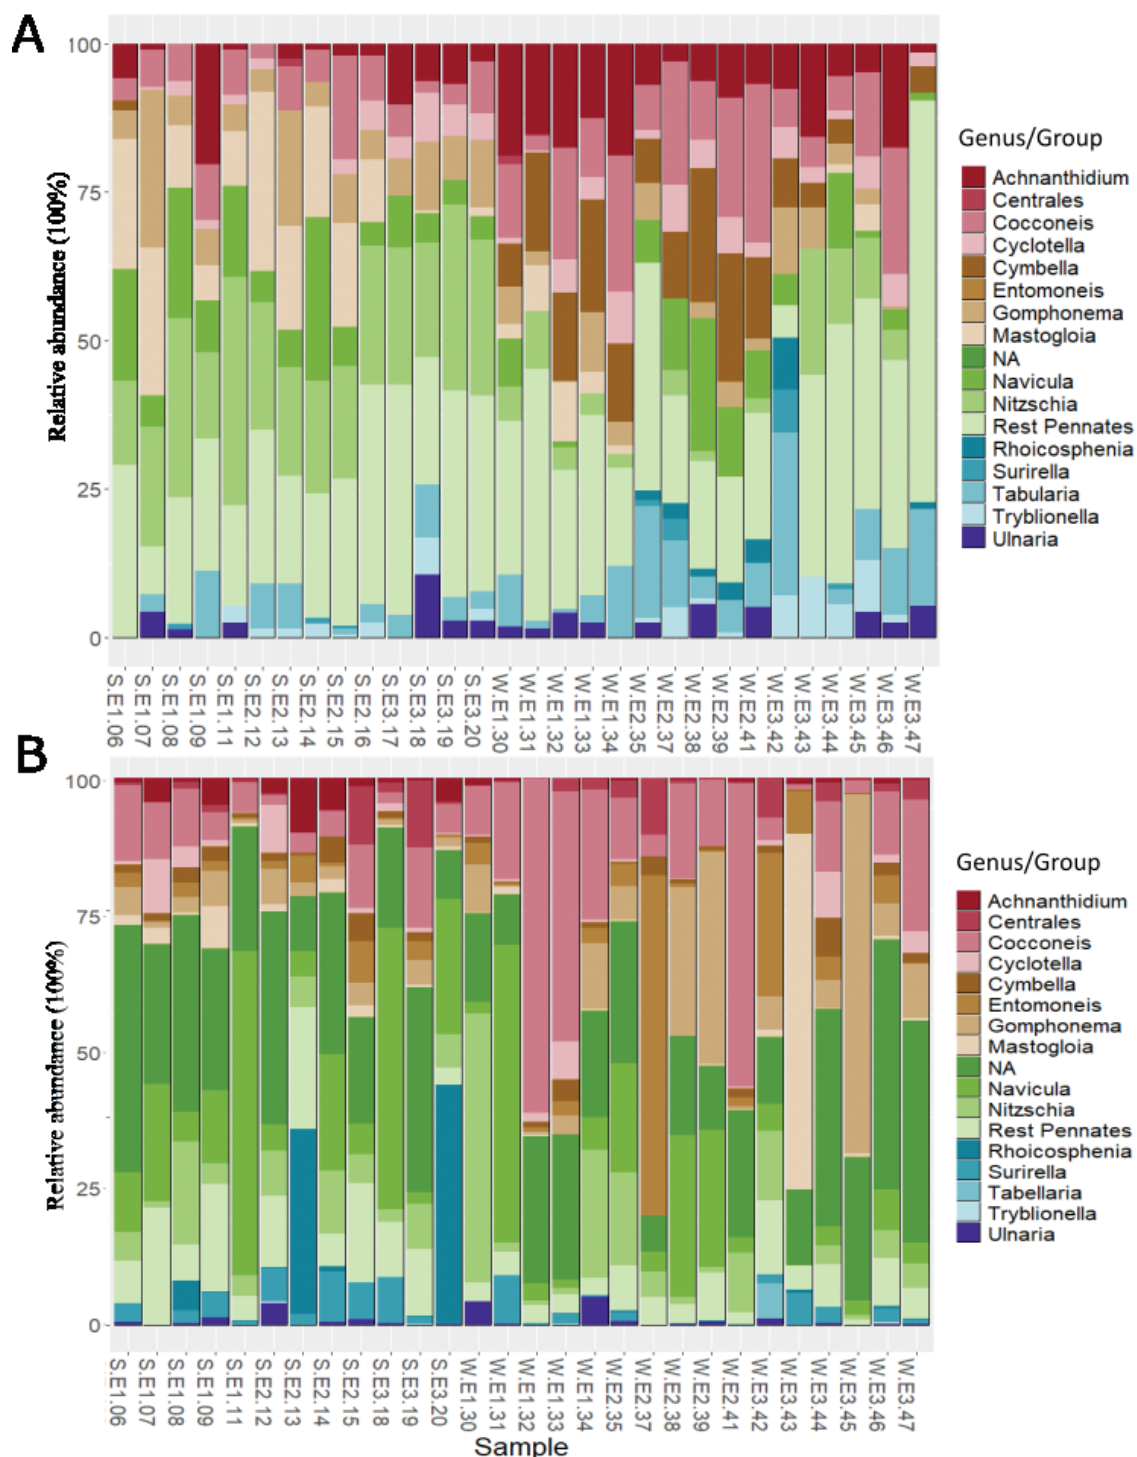

Figure 15. Relative abundance (%) of diatom genera across all sample locations for River Euphrates. **A** Morphology, **B** 18SV4 marker gene. S: summer, W: winter.

Altogether, 60% of the species were successfully identified. 18.5% of the taxa were categorized as 'cf.' (confer). Additionally, 21.5% of the diatom community were designated as 'sp.' (species) pinpointing the need for further taxonomic investigation. This floristic list of this study includes 46 species recorded for the first time for the region (Table 3), underscoring the importance of this study in contributing to understanding the current diversity status of the local diatom flora. These discoveries can be attributed to ongoing alterations in

the rivers' environmental conditions, which prompt the disappearance or emergence of certain species such as the newly described *Prestauroneis furatensis* (Mohamad et al. in press) which was observed in summer samples of the River Euphrates. As expected for epiphytes, pennate diatoms dominated, constituting 93.7% of the identified species, while centric diatoms were only 6.3%. This is consistent with previous findings in freshwater environments (Al-Ahmady et al. 2019; Al-Saedy and Al-Shaheen 2021).

Several taxa of marine origin were recorded, including *Tabularia fasciculata*, *Seminavis strigosa*, *Navicula cf. subagnita*, *Tryblionella granulata*, *T. angustata*, *T. compressa*, *T. calida*, *Surirella striatula*, and *Entomoneis paludosa*. The reason may be the direct connection of the Qurna marsh with the Shatt Al-Arab River, coupled with its reception of water from the Arabian Gulf during high tides, creating a conduit for the migration of numerous marine diatoms to this region, situated around 200 km from the Gulf. This correlation is consistent with Al-Handal's 2010 study. Several brackish diatoms were found, such as *Bacillaria paxillifera*, *Tryblionella hungarica*, *Nitzschia filiformis*, *Navicula salinarum*, *Halamphora coffeaeformis* and *Haslea spicula*, because salinity fluctuates depending on the water flow rate. The years 2009 and 2014 showed an increase in temperatures leading to an enhanced evaporation and subsequently exacerbated the already pressing issue of salinity in the region (Al-Handal 2009; Al-Handal et al. 2014). With less freshwater flowing from the rivers, larger amounts of seawater ingress from the Arabian Gulf and add to the dilemma of salinity.

Nevertheless, in terms of ecological preferences, the distribution of diatom assemblages in the Rivers Tigris and Euphrates showcases a prevalence of freshwater (65.5%), followed by brackish (13.5%) and marine species (10%). This distribution is consistent with previous studies (Al-Handal et al. 2014; Al-Shaheen and Al-Handal 2017; Al-Saedy and Al-Shaheen 2021). The remaining 11% were euryvalent species, exhibiting a broad range of ecological preferences, spanning habitats from freshwater to marine environments, according to the literature (diatombase.org). The presence of taxa with varying, broad or uncertain ecological preferences further emphasizes the complex nature of these river ecosystems which encompass habitats ranging from freshwater to brackish and marine.

### Species composition by metabarcoding analysis

Although metabarcoding has been extensively implemented worldwide in the past decade for diatom analysis, there is only one study (Al-Meshhdany and Hassan 2020) of this kind in the Tigris River in Iraq. Therefore, our study is the first of its kind to compare the traditional microscopic analysis and the molecular analysis (Metabarcoding) between the Rivers Tigris and Euphrates in Iraq. A fragment of 18S barcode gene (18SV4) combined with High-Throughput Sequencing, was employed to elucidate the composition for 47 samples and to compare these findings with traditional microscopic analyses.

This study showed that DNA metabarcoding is an efficient method and a reliable approach for evaluating diatom biodiversity, as it detected a nearly comparable number of genera to the traditional LM method. In contrast, DNA barcoding produced a higher number of ASVs compared to the taxa identified by LM.

This phenomenon can be attributed to several factors. Intraspecific genetic variation within diatom species can result in multiple ASVs being generated from slightly different sequences of the same species. Additionally, diatoms may possess multiple rRNA operons within their genomes, which can evolve at different rates and produce distinct sequences (Schloss 2021; Wang et al. 2024). Sequencing errors and PCR amplification artifacts also contribute to the generation of multiple ASVs from the same species (Kang et al. 2021). Furthermore, the incompleteness of reference databases, which may lack comprehensive or up-to-date sequences, can also lead to an overestimation of species diversity by not fully capturing the genetic variation within species. This highlights the need for more robust reference databases and careful interpretation of metabarcoding results (Schloss 2021).

### Comparison between morphological and molecular results

The LM approach demonstrated greater efficiency in species-level identification. Consequently, the number of species-level identifications is lower in the metabarcoding dataset compared to the morphological analysis data. This finding aligns with Zimmermann et al. (2021), where 385 species were identified using the morphological approach, whereas 221 (*rbcL*) and 160 (18SV4) species were identified, respectively (e.g. Mora et al. 2019; Kulaš et al. 2022; Tapolczai et al. 2024). The differences in species-level identifications between the two methods can be primarily attributed to the gaps present in the reference databases, indicating their incompleteness, as well as the taxonomic inconsistencies within them. For example, in our study, most of the species in the genus *Mastogloia* and *Achnanthydium* given in the morphological results are not present in any reference library.

Interestingly, some taxa observed in metabarcoding were not detected in the morphological analyses, such as *Fistulifera*. These valves might have been destroyed during sample processing, as treatment with Naphrax tend to affect delicate structures (Vermeulen et al. 2012; Pérez-Burillo et al. 2022). Additionally, during the molecular analysis of our samples, *Navicula directa* was notably abundant, a species typically found in marine environments. Interestingly, this species was not observed in the morphological analysis of the same samples, where many marine species are increasingly found in freshwater ecosystems due to rising salinity levels (as mentioned above). The absence of *Navicula directa* in the morphological dataset raises concerns about the effectiveness of the 18SV4 marker used in this molecular analysis. This marker may have limitations in accurately differentiating between species, not only within the *Navicula* genus but also among some other diatom genera. The 18SV4 region is known to exhibit insufficient resolution for distinguishing closely related species due to high genetic similarity of this marker within certain closely related taxonomic groups. Such limitations could lead to overlooking of taxa, highlighting the need for supplementary markers to improve the resolution of molecular analyses.

Furthermore, some taxa with a high abundance and identified microscopically to the species level (e.g., *Navicula recens*, *Navicula rostellata* and *Nitzschia clausii*) which were to be expected in certain samples, had no corresponding match in the metabarcoding inventories. The reason may be the lack of appropriate concentrations of DNA in the corresponding sample.

## Community analysis

Generally, the number of ASVs produced by DNA sequencing significantly differs from the taxa count identified morphologically in the same environmental samples (Pawlowski et al. 2014; Mora et al. 2019). This study revealed that the number of taxa per sample was often higher using metabarcoding compared to microscopy, a finding which aligns with several other studies (e.g., Tapolczai et al. 2024; Rimet et al. 2018). However, while some samples exhibited a higher taxonomic richness, this did not necessarily imply greater diversity. In some cases, metabarcoding identified fewer species compared to microscopy.

Various biological, environmental, and technical factors contribute to the overestimation or underestimation of taxonomic richness in metabarcoding data. The natural infraspecific and intragenomic variability of the barcode marker is considered one of the most significant biological factors influencing overestimation of richness. This poses a particular challenge when a single recognized species or taxonomic indicator encompasses a diverse array of genetic patterns. Sequences corresponding to different genetic patterns within the same taxon may cluster into different ASVs, artificially inflating taxonomic richness (Mora et al. 2019).

NMDS plots of 18SV4 inventories did not show a seasonal effect in the community composition for samples collected from the Rivers Tigris and Euphrates. In contrast, the NMDS plots for morphology revealed a clear seasonal effect distinguishing between summer (dry seasons) and winter (rainy seasons). This discrepancy may be attributed to gaps in the reference databases of DNA barcode sequences, particularly at the species level, which hinder accurate taxonomic assignments.

To address these limitations, it might be valuable to repeat the study using the *rbcL* marker, which has shown promise in providing higher resolution for diatom identification (e.g., Schimani et al. 2023). The *rbcL* marker may help to resolve the discrepancies observed with the 18SV4 marker and offer a clearer understanding of seasonal variations in diatom communities. Additionally, producing unialgal diatom strains from the studied sites and incorporating their data into the study could provide further insights into the diversity and dynamics of diatom populations, as unialgal strains allow for more detailed morphological and genetic analyses (Mohamad et al. 2022). The gaps in reference libraries need to be closed by cultured diatoms of the region to improve the accuracy of species identification, thereby enhancing the overall reliability of the metabarcoding approach in assessing diatom community composition.

## Conclusion

In this study, we investigated the epiphytic diatom assemblages in the Euphrates and Tigris catchment area using the method metabarcoding in comparison with microscopical morphology (LM and SEM). Both methods revealed a high diversity of diatoms, however, significant differences were found in the taxon lists. Our results demonstrate that a combination of metabarcoding and microscopy, increases the detection and identification of diatom species, highlighting the importance of using both approaches complementary. Even in the advent of big advances and successes in the development and standardization of molecular tools for biodiversity assessments and monitoring (Apothéloz-Perret-Gentil et al.

2017), the role of morphology in species discovery and detection remains central. Further studies using additional markers, such as *rbcL*, are recommended to enhance our understanding of diatom diversity. Additionally, diatoms strains isolated from the studied area could provide deeper insights into their ecological roles and responses to environmental changes. Such investigations are essential for illustrating the importance of sustainable ecosystem management and the conservation of the vital resource of water, both regionally and globally. By highlighting the complex biodiversity of diatoms and their sensitivity to environmental shifts, this study underscores the need for effective conservation strategies to maintain the health and sustainability of aquatic ecosystems.
