## Abstract

This work presents a study on the sensitivity of two satellite cloud height retrievals to cloud vertical distribution. The difference in sensitivity is exploited by relating the difference in the retrieved cloud heights to cloud vertical extent. The two cloud height retrievals, performed within the Freie Universität Berlin AATSR MERIS Cloud (FAME-C) algorithm, are based on independent measurements and different retrieval techniques. First, cloud top temperature (CTT) is retrieved from Advanced Along Track Scanning Radiometer (AATSR) measurements in the thermal infrared. Second, cloud top pressure (CTP) is retrieved from Medium Resolution Imaging Spectrometer (MERIS) measurements in the oxygen-A absorption band. Both CTT and CTP are converted to cloud top height (CTH) using atmospheric profiles from a numerical weather prediction model. A sensitivity study using radiative transfer simulations in the near-infrared and thermal infrared were performed to demonstrate the larger impact of the assumed cloud vertical extinction profile on MERIS than on AATSR top-of-atmosphere measurements. The difference in retrieved CTH ( $\Delta$ CTH) from AATSR and MERIS are related to cloud vertical extent (CVE) as observed by ground-based lidar and radar at three ARM sites. To increase the impact of the cloud vertical extinction profile on the MERIS-CTP retrievals, single-layer and geometrically thin clouds are assumed in the forward model. The results of the comparison to the ground-based observations were separated into single-layer and multi-layer cloud cases. Analogous to previous findings, the MERIS-CTP retrievals appear to be close to pressure levels in the middle of the cloud. Assuming a linear relationship, the  $\Delta$ CTH multiplied by 2.5 gives an estimate on the CVE for single-layer clouds. The relationship is weaker for multi-layer clouds. Due to large variations of cloud vertical extinction profiles occurring in nature, a quantitative estimate of the cloud vertical extent is accompanied with large uncertainties. Yet, estimates of the CVE can contribute to the characterization of a cloudy scene. To demonstrate the plausibility of the approach, an estimate of the CVE was applied to a case study. In light of the follow-up mission Sentinel-3 with AATSR and MERIS like

instruments, Sea and Land Surface Temperature Radiometer (SLSTR) and (Ocean and Land Colour Instrument) OLCI, respectively, for which the FAME-C algorithm can be easily adapted, a more accurate estimate of the CVE can be expected. OLCI will have three channels in the oxygen-A absorption band, thus providing more pieces of information on the cloud vertical extinction profile.

## 1 Introduction

The vertical distribution of clouds plays an important role in both meteorological and climatological applications. It can be an indicator of the meteorological conditions, (thermo-)dynamical and micro-physical processes, in which a cloud forms (e.g. Yin, 2013; Yuan et al., 2011; Luo et al., 2009). Further, the cloud vertical distribution affects radiative and latent heating fluxes, which in turn, affect the large-scale atmospheric circulation and precipitation processes (e.g. Wang and Rossow, 1998; Li et al., 2014).

Cloud-climate feedbacks are the main source of uncertainty in climate models (Flato et al., 2013). Accurate characterization of vertical distributions of different cloud types are needed to evaluate and improve the modeling of cloud-climate feedbacks and thus climate change projections. In Jiang et al. (2012) A train observations are used to quantify the performances of models that participate in the Coupled Model Intercomparison Project (CMIP) in simulating clouds at different vertical levels. The results were submitted to the Intergovernmental Panel on Climate Change (IPCC) reports, and improvements in the simulation of ice water path, for example, were found in the comparison of Phase 5 CMIP model results compared to Phase 3 CMIP3 model results. Largest differences and spreads between the CMIP5 models and A-train observations of cloud water content profiles are found at upper tropospheric levels.

Cloud vertical distribution can be described by a set of cloud parameters, such as cloud top height and cloud base height, and subsequently cloud geometrical thickness, and the number of distinct cloud layers in an air column. These cloud parameters can

be observed by a set of remote-sensing techniques using observations from ground-based or space-born instruments.

From ground-based observations information on cloud vertical distribution can be derived from, e.g., human observers, lidars, and radars. The first two only observe the cloud base height, while radar can observe the cloud vertical profile. However, the spatial coverage of these ground-based observations are mainly limited to land areas in the Northern Hemisphere. Global and accurate observations of cloud vertical distribution are necessary for an improved understanding of cloud processes, and subsequently improved representations of these processes in climate models. Satellite observations can provide this global coverage. In 2005, the active instruments CPR (Cloud Profiling radar) and CALIOP (Cloud-Aerosol Lidar with Orthogonal Polarization), on polar-orbiting satellites CloudSat (Stephens et al., 2002) and CALIPSO (Cloud-Aerosol Lidar and Infrared Pathfinder Satellite Observations) (Winker et al., 2003), respectively, as part of the A-train constellation, were launched. They provided first radar and lidar measurements on cloud and aerosol vertical profiles on a global scale. Since then both instruments have given the atmospheric research community many new insights on clouds and aerosols (e.g. Mace et al., 2007; Sassen et al., 2008) and their observations were extensively used in many evaluation studies (e.g. Naud et al., 2010; Weisz et al., 2007). However, they have a poor spatial coverage due to the nadir-only measurements.

Satellite observations from passive instruments have a larger spatial coverage. However, here the cloud properties are retrieved from information coming mainly from upper cloud layers, such as cloud top temperature, or they represent an integrated property, such as cloud water path. A number of satellite remote sensing techniques exist that retrieve cloud top heights (CTHs) from measurements of passive imagers. For example, cloud top height retrievals from thermal infrared (TIR) measurements have been performed using the CO<sub>2</sub> slicing technique (e.g. Menzel et al., 2008) or with brightness temperature (BT) measurements in window channels (Hamann et al., 2014) (TBD extent refs). Further, cloud top heights can be obtained from stereo, which is based on

Interactive Discussion

the parallax effect occurring between cloud observations from different viewing angles (e.g. Moroney et al., 2002). In Wu et al. (2009) the vertical and latitudinal monthly mean of the vertically distributed volume cloud occurrence frequency were compared among various passive and active satellite instruments. Here, also a discussion on the strengths and weaknesses of the various passive CTH retrieval techniques is given. Also in Naud et al. (2005) intercomparisons were performed for several passive and active cloud top height retrievals.

In 1961, Yamamoto and Wark (1961) proposed to retrieve cloud top altitude from space by measuring the absorption of reflected solar radiation in the oxygen-A absorption band located at around 760 nm. In the method the strength of the absorption of radiation in the oxygen-A band is related to the cloud top pressure, via the mean photon path length. Later in the 1960s, first satellite retrievals using the oxygen-A absorption band showed that the enhancement of photon path length needs to be taken into account for accurate cloud top pressure retrievals (Saiedy et al., 1967). The impact of the cloud vertical inhomogeneity on the accuracy of the cloud top pressure retrievals has also been recognized in a number of theoretical studies (Fischer and Grassl, 1991; Rozanov and Kokhanovsky, 2004; Preusker and Lindstrot, 2009). Various cloud height retrievals based on measurements in the oxygen-A absorption band are described in, e.g., Wang et al. (2008); Rozanov and Kokhanovsky (2004); Koelemeijer et al. (2002); Vanbauce et al. (1998). In most of these cloud height retrievals, multiple scattering inside the cloud layer is neglected or homogeneous cloud vertical profiles are assumed. This leads to the retrieval of a so called apparent cloud height which corresponds to a pressure level somewhere in the middle of the cloud rather than to the cloud top.

The Freie Universität Berlin AATSR MERIS Cloud (FAME-C) algorithm retrieves cloud top pressures (CTPs) from radiance measurements of the Medium Resolution Imaging Spectrometer (MERIS) in the oxygen-A band as well as cloud top temperatures (CTTs) from BT measurements in two TIR channels of the Advanced Along Track Scanning Radiometer (AATSR). Both instruments are mounted on the polar-orbiting

Interactive Discussion

Environmental satellite (Envisat). FAME-C is developed within the frame of the ESA Climate Change Initiative (Hollmann et al., 2013). Within FAME-C, mean cloud vertical extinction profiles derived from 1 year of data from CPR onboard CloudSat combined with MODIS data were used in order to account for a more realistic description of the multiple scattering inside the cloud. The extinction profiles were derived for nine cloud types taken from the ISCCP cloud classification (Rossow and Schiffer, 1999), which is based on total cloud optical thickness (COT) and cloud top pressure. For two case studies with vertically extended clouds it was shown that the choice of the cloud vertical extinction profile can have a large impact on the retrieved MERIS cloud top pressure. Comparisons to CPR cloud heights showed that on average the bias was reduced by a large amount when using the mean CPR profiles instead of vertically homogeneous profiles (HOM) (Henken et al., 2013). This can be mainly attributed to lower extinction values in the upper cloud layers for the CPR profiles than for the HOM profiles, which appears to be closer to reality for these vertically extended clouds. However, for individual cloud scenes, the CTP retrieval can still have a large bias if the profile assumption is wrong. The TIR cloud height retrievals are less affected by the profile assumption.

In this study we aim to make use of the difference between the two different cloud height retrievals, since it obviously carries information on the cloud vertical distribution. The method of combining a cloud height retrieval from measurements in the oxygen-A absorption band with an independent cloud height retrieval to retrieve information on the cloud vertical distribution was suggested by others before (e.g. Vanbaucé et al., 2003; Kokhanovsky and Rozanov, 2005; Lindström et al., 2010b). In order to maximize the impact of the desired parameter, which is the cloud vertical extent (CVE), on the signal, which is here the difference between the cloud height retrievals, we limit the correction for in-cloud scattering in the MERIS-CTP retrieval. For this purpose, the FAME-C algorithm was extended to also retrieve the cloud height assuming a single-layer cloud with a geometrical thickness of 20 hPa, which can be considered to be close to a solid reflector for optically thick clouds. Ground-based observations from lidar and

radar at three Atmospheric Radiation Measurement (ARM) program's site are used to relate the retrieved cloud height differences to observed cloud vertical extent.

The structure of this paper is as follows. First, a sensitivity study is presented for which radiative transfer simulations in the near-infrared and thermal infrared part of the spectrum for clouds with different cloud vertical extinction profiles are performed and compared. Second, the ground-based and satellite observations are presented. Next, the method for the comparison of the ground-based data and satellite data is described. Then, the results are presented and discussed. In addition, the application of the method is shown in a case study. Last, conclusions are given.

## 2 Sensitivity study

For cloud particles, the single scattering albedo is close to one in the visible (VIS) and near-infrared (NIR) part of the spectrum and therefore little absorption of photons by cloud particles takes place. In the thermal infrared (TIR) part of the spectrum the single scattering albedo has values clearly less than one, so most photons will be absorbed by cloud particles after just a few scattering events. Thus in the satellite-based TIR CTH retrievals the signal mostly stems from the upper part of the clouds, while the VIS/NIR CTH retrievals are affected by a larger part of the cloudy atmosphere. Therefore, the assumed cloud vertical extinction profiles in the retrievals are expected to have a larger impact on the VIS/NIR CTH retrieval than on the TIR CTH retrievals.

To investigate the difference in impact of cloud vertical extinction profile on cloud top height retrieved with radiances from NIR spectral bands and BTs from a window TIR spectral band, radiative transfer simulations have been performed using the model Matrix Operator Model (MOMO). MOMO has been developed at the Freie Universität Berlin (Fell and Fischer, 2001; Hollstein and Fischer, 2012). Recently, MOMO was extended through the implementation of thermal emission of radiation by the surface and (cloudy) atmospheric layers, allowing for accurate simulations in the thermal infrared (Doppler et al., 2014a). The spectral response function of the AATSR 10.8  $\mu\text{m}$  channel

was used for the simulations in the TIR. The spectral response functions of the MERIS window channel 10 centered at 753 nm and the oxygen-A absorption channel 11 centered at 761 nm, were used to simulate the ratio of the absorption channel over the window channel, shown in Fig. 1.

5 Radiative transfer simulations in a cloudy atmosphere are performed assuming a plane-parallel atmosphere with a vertical resolution of 20 hPa in the troposphere. A US Standard Atmosphere was assumed in the simulations (McClatchey et al., 1972). Furthermore, the surface is modelled as a Lambertian reflector with a surface albedo of 0.02 and a surface pressure of 1013 hPa. A Rayleigh optical thickness of 0.026 is  
10 taken. To compute the absorption coefficients of the atmospheric gases, the  $k$  distribution method is used (Bennartz and Fischer, 2000; Doppler et al., 2014b), where the information on the position and width of absorption lines is taken from the HITRAN database (Rothman et al., 2009).

Two types of cloud vertical extinction profiles are assumed in the simulations. For the  
15 first type, 1 year of data from the combined CPR and MODIS product (2B-TAU, Polonsky et al., 2008) was analyzed. The clouds observed by CPR and MODIS were sorted with respect to their CTP and COT, resulting in 9 different cloud types, using the ISCCP cloud type classification (Rossow and Schiffer, 1999). For each cloud type, the average vertical profile of extinction and the average vertical extent were determined (Henken  
20 et al., 2013). The derived normalized extinction profiles (from here on called CPR profiles/clouds) were then used in the MOMO radiative transfer simulations to generate LUTs for each of the nine cloud types. The LUTs serve as forward models in the cloud height retrievals. For the second type, vertically homogeneous extinction profiles are assumed (from here on called HOM profiles/clouds). As an additional LUT dimension,  
25 each cloud is modeled with varying vertical extents, starting with a cloud geometrical thickness (CGT) of 20 hPa and ending at the maximum possible geometrical thickness.

For cloud layers below 440 hPa water droplets are assumed with a fixed effective radius of 10  $\mu\text{m}$ , the single-scattering properties were computed using a Mie code (Wiscombe, 1980). For cloud layers above 440 hPa ice crystals are assumed with a fixed

effective radius of 40  $\mu\text{m}$ , assuming single-scattering properties described in Baum et al. (2005).

For selected CTP and COT combinations, the simulated results (MERIS radiance ratio and AATSR BT) at the top of the atmosphere (TOA) using CPR profiles were compared to the simulated results using HOM profiles with varying CGT. Figure 2 shows the combinations of CTP and CGT of HOM clouds resulting in the smallest deviation in the simulated signal from the case of a CPR cloud with CTP of 600 hPa, for both AATSR and MERIS. In general, the difference between the effective HOM-CTP and CPR-CTP is smaller for AATSR than MERIS, especially for optically thick clouds. The largest difference between the effective HOM-CTP and the CPR-CTP is found for geometrically thin clouds with COT = 10 for MERIS, while for AATSR the largest difference is found for optically thin clouds. The higher CTPs of the HOM clouds can be explained by the fact that for clouds with the CPR profiles, the extinction of the upper cloud layers is lower than the extinction of the upper cloud layers for clouds with a HOM profile. In order to get the same TOA signal as the CPR-cloud, the HOM-cloud needs to be placed at a lower altitude. Alternatively, the CGT of the HOM-cloud can be increased. For both MERIS and AATSR, the HOM-CTP approaches the CPR-CTP for increasing CGT, and even underestimates the CTP for clouds extending down to the surface. Note that for the very optically thick clouds (COT = 100), the HOM-CTP does not reach the CPR-CTP, even for vertically extended clouds. Missing points relate to CPR simulation results that did not fall within the range of HOM-CTP results for the assumed CGT. For optically thick clouds, the dependence of the HOM-CTP on the CGT is much weaker for AATSR than for MERIS, due to the fact that in the TIR the contribution from lower cloud layers to the TOA signal is weaker, and thus the shape of the entire cloud vertical extinction profile plays a less important role in the TIR than in the NIR.

The sensitivity of the effective HOM-CTP to the CGT, i.e., the change in the effective HOM-CTP for an increase of the CGT with 50 hPa, is summarized in Fig. 3 for various cloud types. The sensitivity was computed by simply applying a linear fit to each line that corresponds to a fixed COT and varying CGT (as can be seen in Fig. 2). This was

done for a low (800 hPa), mid-level (600 hPa), and high (300 hPa) cloud and a range of COTs. For MERIS, the sensitivity is largest for clouds with COT = 10. This can be explained as follows. For optically thin clouds, a large part of the radiation arriving at TOA has traversed the cloud without interaction with cloud particles, thus not affected by the vertical extinction profile of the cloud at all. For optically very thick clouds, the contribution from upper cloud layers will dominate the TOA signal even for geometrically thicker clouds, thus the influence of the entire vertical extinction profile is smaller. For optically moderate thick clouds, the full vertical extinction profile has an impact on the TOA signal, while the contribution of the earth surface and the lower atmosphere is suppressed. For AATSR, the sensitivity decreases for increasing COT, indicating that the assumed shape of the extinction profile is of less importance for optically thick clouds due to contributions to the TOA signal arising mainly from upper cloud layers. In summary, the MERIS sensitivity is always higher than the AATSR sensitivity for COT > 5.

Figure 4 shows the AATSR sensitivity of the effective HOM-CTP to the CGT for which the physical CTPs are substituted by radiometric CTPs. For each cloud type, the CTP is taken at the pressure level for which COT = 1. This is the radiometric cloud top, when assuming no scattering and a linear dependency of the Planck function on the COT. Again linear fits were applied. Now, the sensitivity is largest for clouds with COTs around 5. For optically thinner clouds, the CPR and HOM radiometric cloud heights are located more closely to each other than the physical cloud heights. Note, considering scattering and contribution to the TOA signal from lower cloud layers, the actual radiometric cloud top will be located at more than one COT into the cloud (Sherwood et al., 2004).

This exercise confirms that one can expect cloud height retrievals from MERIS to be more affected by the cloud vertical extinction profiles than the AATSR cloud height retrievals, at least for optically thick clouds.

### 3 Data

#### 3.1 AATSR and MERIS

Within FAME-C two independent cloud top height products are retrieved on a pixel-basis: AATSR cloud top temperature and MERIS cloud top pressure. AATSR and MERIS are two passive imagers mounted on the polar-orbiting satellite Envisat, launched in March 2002 and operational until April 2012. Envisat flies in a sun-synchronous orbit with an equator crossing time of 10:00 LT, descending node.

In the MERIS-CTP retrieval the transmission within the oxygen-A band is estimated from the ratio of channel 11 and window channel 10. In the AATSR cloud top temperature retrieval, brightness temperature measurements at 10.8 and 12  $\mu\text{m}$  are used to retrieve cloud top temperature. Atmospheric profiles from a numerical weather model (NWP) reanalysis are used to convert cloud top temperature and cloud top pressure to cloud top height. The cloud top temperature is compared to the temperature profile and the minimum height at which the cloud top temperature equals the atmospheric temperature is assumed to be the cloud top height. For optically thick clouds, CTT will be similar to the measured 10.8  $\mu\text{m}$  brightness temperature, corrected for the atmosphere. For optically thin clouds, the cloud emissivity is taken into account, which will result in a CTT that is lower than the measured 10.8  $\mu\text{m}$  brightness temperature. More information on the two independent cloud top height retrievals can be found in Carbajal Henken et al. (2014).

For this study, the FAME-C algorithm was extended to also provide retrieved cloud top temperature from AATSR, cloud top pressure from MERIS, and accompanying cloud top heights, assuming a single-layer and vertically homogeneous cloud with a geometrical thickness of 20 hPa. For optically thick clouds, this comes close to a solid reflector. Further adjustments in the FAME-C algorithm include the use of a new cloud masking method (Hollstein et al., 2014), which is in first order aimed to reproduce the former cloud masking method but with higher computational efficiency. Before applying the cloud mask, the AATSR and MERIS measurements are collocated using the BEAM

toolbox (Fomferra and Brockmann, 2005; ESA, 2015). In addition, the 3rd reprocessing for AATSR data were used and an empirical nonlinear correction was applied to the 12  $\mu\text{m}$  channel (Smith, 2014). Further, a straylight correction was performed for the MERIS measurements (Lindstrot et al., 2010a). Last, a pixel-based multi-layer cloud detection, i.e., thin cirrus over low-level water clouds, based on Pavolonis and Heidinger (2004) is implemented. Note, no distinct retrievals for multi-layer cloud cases are performed, the pixels are simply flagged as multi-layer cloud or not.

### 3.2 ARM millimeter cloud radar and micropulse lidar

The active remote sensing of clouds (ARSCL) product from ground-based observations performed at the Atmospheric Radiation Measurement (ARM) program's site in the Southern Great Plains (SGP), three sites in the Tropical Western Pacific (TWP), and North Slope Alaska (NSA) is used. It provides cloud boundary heights, i.e., cloud base height and cloud top height, for up to 10 cloud layers (Clothiaux et al., 2000). The cloud boundary heights are determined from a combination of measurements from the Micropulse Lidar (MPL) and Millimeter Cloud Radar (MMCR) and are provided at a vertical resolution of 45 m and a temporal resolution of 10 s.

With the radar, vertically extended and multiple cloud layers can be penetrated and observed, while the laser beam of the lidar is attenuated quite fast and thus can not penetrate much further beyond the lowest cloud base in case of optically thick clouds. The radar is less sensitive to small cloud particles and optically thin clouds, often occurring at great heights. These clouds can be observed well with the lidar system. Furthermore, radar observations of cloud base heights are often hampered in the presence of large non-hydrometeor particles, such as insects. They might be observed as low-level clouds. For large concentrations of non-hydrometeors, also the lidar observations of cloud base become problematic. In case of heavy precipitation both radar and lidar observations are not useful (Clothiaux et al., 2000).

## 4 Method

To study the relationship between the difference in the two FAME-C cloud height retrievals and the cloud vertical extent as observed by ground-based lidar and radar instruments, the satellite and ground-based observations of clouds need to be matched accordingly.

For each ARM site the satellite orbit segments of all Envisat overpasses with available FAME-C level-2 cloud properties for the years 2003–2011 are collected. The ground-based observations and satellite observations occur on different spatial scales, thus temporal averaging for the ARSCL products and spatial averaging for the FAME-C products is performed. From the ARSCL data, the height of the top height of the highest cloud layer and the base height of the lowest cloud layer are collected for a 5 min time period centered at the time of overflight of Envisat. The CVE is derived from the difference between the two extreme cloud boundaries. In addition, also the number of cloud layers and the distance between the cloud layers is extracted from the ARSCL data. From the FAME-C data, a 9 by 9 pixel box centered at the center pixel was taken to compute mean vertical cloud top heights. The pixel with the minimum distance to the location of the radar was selected as the center pixel. Using the ARSCL cloud top height and the satellite instrument viewing geometry, parallax correction is applied to adjust the center pixel. This was performed separately for AATRS-CTT and MERIS-CTP.

In the evaluation, only cases with enough successfully retrieved cloud height products within the satellite pixel box (> 80 %) and within the 5 min time period (> 80 %) are selected. More precisely, only pixels for which the FAME-C cloud top heights that converged successfully with a cost < 20 are considered. For the ARSCL products at least 80 % of the time steps need to have a cloud base height determined by the lidar and a cloud top height either determined by radar or lidar. In addition, the temporal and spatial variability should not be too large, i.e., the SD of the selected cloud top heights should be < 1 km. The selection criteria were chosen in such a way that the study is

directed towards mainly overcast cloudy scenes with spatially and temporally uniform cloud top heights, but still a large enough number of cases remain available. It results in a total of 153 selected cases, which is less than 6 % of all Envisat overflights for which the AATSR swath passes over one of the ARM sites within the years 2003–2011. Note, both the ARSCL products, depending on the ARM site, and FAME-C products do not cover the full time period of the years 2003–2011. There were  $X$ ,  $Y$  and  $Z$  valid cases found for the SGP, TWP and NSA ARM sites, respectively.

## 5 Results and discussion

Figure 5 shows the results presented separately for single-layer and multi-layer clouds. Single-layer cloud cases are defined as cases where at least 80 % of the pixels in the satellite pixel box have not been identified as multi-layer clouds according to the multi-layer test implemented in FAME-C. Multi-layer cloud cases are defined as cases where at least 80 % of the pixels in the pixel box have been identified as multi-layer clouds.

One can immediately see that on average the difference in AATSR and MERIS CTHs ( $\Delta$ CTH) increases with increasing CVE as observed by the radar and lidar. This is true for both single-layer and multi-layer clouds, though the correlation is higher for single-layer clouds. Most obvious outliers mainly represent cases where the mean COT < 10. As one would expect from the climatic regimes, the most vertically extended clouds are found at the TWP sites, followed by the SGP site. The dependence of the  $\Delta$ CTH on the CVE is strongest for the SGP site for optically thick clouds. There are several cases with optically thin clouds for which the MERIS-CTH is higher than the AATSR-CTH. This is an indication of incorrect AATSR-CTT retrievals and might partly be related to wrong assumptions in the forward model which are related to estimates of the cloud emissivity and ignoring multiple scattering. For single-layer low-level clouds, the derivation of the AATSR-CTH might be ambiguous or missed if the temperature profile does not represent a temperature inversion accurately enough. This leads to a positive  $\Delta$ CTH for clouds with observed small vertical extents.

Interactive Discussion

A linear fit was computed for the cases with  $COT > 10$ , also shown as the black solid line in the figures. Variability around the fitted lines present an indication of the variability of cloud vertical profiles/distributions that occur in nature. However, incorrect matching of the observations (not observing the same cloud volume) might also have an impact on the results. For single-layer clouds a factor of 2.5 is found between  $\Delta CTH$  and CVE. Knowing that on average the retrieved AATSR cloud top temperature is close to, but just below the cloud top, the difference between the AATSR-CTH and MERIS-CTH is about half of the vertical extent of the cloud. This corresponds well to the findings of Ferlay et al. (2010) where it was found that the POLDER (Polarization and Directionality of the Earth's Reflectances) cloud oxygen pressure is on average close to the pressure level at the geometrical middle of the cloud. The multi-layer cloud cases show a weaker dependence of the  $\Delta CTH$  on the CVE, which can be explained by considering that for these cloud cases also a large part of the vertical column consists of cloud-free atmosphere. Here, the mean photon path length in the NIR is not increased due to in-cloud scattering. Thus, the effect of the cloud vertical distribution is suppressed relative to vertically extended single-layer clouds.

To demonstrate the difference in retrieved cloud top height products assuming CPR cloud vertical profiles and HOM cloud vertical profiles they were compared to the radar-based CTHs. Indeed, AATSR-CTH shows a negative bias. As expected, the difference in biases between CPR and HOM, and also between single-layer and multi-layer clouds are small, since AATSR tends to see the upper cloud layers and therefore is less dependent on the cloud vertical extinction profile and vertical extent. For MERIS-CTH, the difference in biases between CPR and HOM is large, with a small negative bias for CPR and a large negative bias for HOM. When only including cases where the mean  $COT > 5$ , the absolute biases decrease slightly for all except MERIS-CTH HOM. For AATSR-CTH the root mean square deviation (RMSD) of HOM and CPR show similar values and are smallest for single-layer clouds with  $COT > 5$ . The RMSD of MERIS-CTH HOM is larger than for MERIS-CTH CPR, and overall largest for multi-layer clouds.

## 6 Case study

The estimate of CVE from the relationship found in the former section has been applied to Envisat observations of Hurricane *Dean*, which moved across the Caribbean Sea in August 2007. Hurricanes are dynamical cloud systems which consist of parts with dense and vertically extended clouds in the main part of the system, multi-layer clouds, optically thick and thin cirrus clouds, and single-layer low-level clouds at the outer regions of the system.

Figure 6 shows the true color image of the hurricane, as well as the multi-layer flag, cloud top height retrieved from AATSR and the estimate of the vertical extent of the system. In the inner area no successful retrievals were performed within FAME-C partly due to no convergence and partly due to saturation occurring in the AATSR IR channels. This is also the area where the hurricane eye is located. The estimated CVE along the black line can be qualitatively compared to observations from CPR. The cross-section as well as the CPR radar reflectivities are shown in Fig. 6. The Envisat cross-sections slightly “touches” the main part of the system. Note that the CloudSat overpass is about three hours later than Envisat. The cloud system will have moved mostly towards the west as well as rotated. Therefore, no pixel-based comparison is possible. The overpass of CloudSat is shown in the upper left panel of Fig. 6 with the dotted red line. Further, CPR observations of low-level water clouds near the surface can be problematic due to ground clutter.

The vertical extent is estimated to be up to 15 km for the main part of the hurricane, which agrees well with the maximum height as observed by CPR. The maximum estimated vertical extent near the main part of the system (between latitude 14 and 16°) appears to be underestimated when comparing to CPR observations. At around latitude 14° and longitude 63° there is an area for which the estimated extent is smaller (about 6 km), while for this area still a height of up to 15 km is retrieved. This might be the dense part of the cirrus shield where the hurricane does not extend down to the surface anymore. The area south of the main part of the hurricane appears to be

dominated by low-level clouds with some thin cirrus aloft. Here, the estimated CVE is mostly small ( $< 5$  km). Directly north of the main part of the hurricane, where the spiral outflow of thin cirrus is located, the CVE is also low ( $< 3$  km). In general, the estimated vertical extent is within several kilometers of the cloud top height for the main part of the system as well as for optically thick clouds (the very bright areas in the true color image). Further, the variability in the estimated CVE is much larger than the variability in the retrieved cloud top height. This is in agreement with the fact that the main part of a hurricane consists of vertically extended clouds (from the tropopause to the surface), while areas directly surrounding this main part consist of a very dense cirrus shield with bands of clouds below. There is an indication that in case of thin cirrus above low-level clouds, occurring in the outer regions of the system, the estimated CVE is well below the distance between the two cloud layers.

## 7 Summary and outlook

This study presents the evaluation of differences between two cloud height retrievals that are based on independent techniques, and relating the differences to cloud vertical extend as observed by ground-based active instruments. The cloud vertical extent is an additional parameter to the cloud top height, both parameters describing the cloud vertical distribution. As suggested by others before, the combined use of the cloud pressure retrieval in the oxygen-A absorption band with an independent cloud height retrieval, here the cloud top temperature from thermal infrared measurements, could potentially be used to characterize the vertical distribution of observed clouds. Measurements from the passive imagers AATSR and MERIS onboard the polar-orbiting satellite Envisat were used in the FAME-C algorithm. Cloud top temperature is retrieved using brightness temperature measurements from two AATSR thermal infrared channels, while cloud top pressure is retrieved with the use of the ratio of the MERIS channel in the oxygen-A absorption band and a near-by window channel.

Interactive Discussion

Due to larger mean in-cloud photon penetration depths for shortwave radiation than for longwave radiation, the sensitivity of the latter retrieval (in the NIR) to the cloud vertical extinction profile is larger than for the former retrieval (in the TIR). This was shown in a sensitivity study where simulations results from the radiative transfer model MOMO for homogeneous and inhomogeneous cloud vertical extinction profiles are compared, for both simulations using MERIS and AATSR spectral response functions. The inhomogeneous profiles are derived from combined CPR and MODIS data. The effective cloud top pressure of the homogeneous clouds with predefined cloud geometrical thickness was derived by comparing the simulated TOA signals of both cloud types. The results confirm that in general, the MERIS effective HOM-CTP is more sensitive to a change in the CGT than AATSR. For both AATSR and MERIS simulations, this sensitivity decreases for increasing COT.

The differences between the MERIS-CTP and AATSR-CTT, both converted to CTH using atmospheric profiles from a numerical weather prediction model, were compared to the cloud vertical extent. In the MERIS-CTP retrieval a single-layer, vertically homogeneous and geometrically thin cloud was assumed to suppress the correction for multi-scattering in the cloud. This was done to increase the impact of the cloud vertical extent on the CTH difference. The extent is defined as the distance between the top height of the highest cloud layer and the base height of the lowest cloud layer. These cloud boundaries are extracted from the ARSCL cloud product based on ground-based radar and lidar observations. A comparison strategy was developed whereby spatial averaging is applied to the satellite products and temporal averaging to the ARSCL products. Only cases with a high cloud cover and limited spatial and temporal variability in the cloud height products are selected. Comparisons were performed at three ARM sites covering different climate regimes, surface conditions and sun-satellite viewing geometry. Results were separated into single-layer and multi-layer cloud cases. It was shown that the difference in CTHs increases with increasing cloud vertical extent for both single-layer and multi-layer clouds, though the relation appears stronger for single-layer clouds. Applying a linear fit to the results with COT > 10 indicates that

Interactive Discussion

a rough estimate of the cloud vertical extent can be obtained by multiplying the CTH difference by a factor of 2.5. If we assume that AATSR-CTH is close to but a bit lower than the physical cloud top (this was indicated by a small negative bias compared to radar CTH), than the MERIS-CTH is close to the geometrical center of the cloud top.

5 Similar findings were found in other studies related to cloud pressure retrievals using measurements in the oxygen-A absorption band. The large variability in cloud vertical extinction profiles occurring in nature and the use of only one measurement in the oxygen-A absorption band limits the accuracy of cloud vertical extent estimates. However, by using a simple linear relationship a rough estimate of the cloud vertical extent can be made allowing for at least a qualitative interpretation of a cloudy scene. An estimate of cloud vertical extent is automatically an estimate of the cloud base height of the lower cloud layer. As a demonstration of the plausability of the approach, estimates of the cloud vertical extent for a cloudy scene were performed within a case study.

10 A limited number of cases was exploited mainly due to filtering out observations of inhomogeneous cloud fields in space and time. Comparisons to observations of cloud vertical extent from CPR on CloudSat and CALIOP on CALIPSO can be performed next. However, matching overpasses of Envisat and A-train only occurred at high latitudes for which CTH retrievals are complicated due to snow/ice surfaces and large solar zenith angles. Moreover, the different satellite viewing geometries in the presence of inhomogeneous cloud fields complicate the matching of Envisat and A-train observations.

15 The impact of future improvements/updates in the FAME-C algorithm on the cloud height retrievals will be investigated. Such changes will include an updated version of RTTOV (and coefficient files) as well as an improved cloud phase detection and a new cloud masking method.

25 Follow-up mission Sentinel-3, planned to be launched in 2015, will carry the AATSR and MERIS like instruments, Sea and Land Surface Temperature Radiometer (SLSTR) and the Ocean and Land Colour Instrument (OLCI), respectively. Thus making FAME-C applicable to those measurements as well. Three channels in the oxygen-A absorption

band are planned for OLCI. Several channels can help to separate signals coming from different parts of the cloudy atmosphere or from the surface, potentially allowing for retrieving more information on the cloud vertical distribution compared to one channel.

*Acknowledgements.* The authors would like to thank ESA for providing the funding for this study within the frame of the ESA CCI Cloud project as well as the Bundesministerium für Bildung und Forschung for providing funding in the framework of the HD(CP)<sup>2</sup> project. Also, the authors would like to thank the ARM Program Climate Research Facility for providing the ARSCL data.

## Cloud extend

C. K. Carbajal Henken  
et al.

**Table 1.** Resulting biases and root mean square deviation (RMSD) from the comparison between the FAME-C cloud top heights and radar/lidar derived cloud top heights. Presented separately for single-layer clouds (Single) and multi-layer clouds (Multi) as well as for FAME-C cloud top heights retrieved using 1 homogeneous cloud layer (HOM) and the CPR vertical cloud profiles (CPR).

		Bias [km]		RMSD [km]	
		Single	Multi	Single	Multi
AATSR-CTH	CPR	-0.88	-1.58	2.38	2.89
	HOM	-1.20	-1.58	2.63	2.89
MERIS-CTH	CPR	-0.27	-1.76	2.51	4.03
	HOM	-2.44	-4.50	3.57	5.44
AATSR-CTH, COT > 5	CPR	-0.56	-1.55	1.99	2.86
	HOM	-0.62	-1.56	1.98	2.83
MERIS-CTH, COT > 5	CPR	-0.22	-1.71	2.57	3.99
	HOM	-2.71	-4.42	3.81	5.38

**Figure 6.** View on hurricane Dean on 17 August 2007. Top left: RGB image. Top right: FAME-C multi-layer cloud flag. Bottom left: retrieved AATSR cloud top height. Bottom right: estimated cloud vertical extent. The solid black line and the dotted red line show the AATSR-MERIS and CloudSat cross-section, respectively, as presented in Fig. 7. Note, the CloudSat overpass occurred about 3 h later than the AATSR-MERIS observations presented here.

## Cloud extend

C. K. Carbajal Henken  
et al.

**Figure 7.** Cross-section of hurricane Dean (17 August 2007). Top: estimated cloud vertical extent from FAME-C cloud heights. Bottom: radar reflectivity from CPR on CloudSat. The blue dots show the height of the most upper layer identified as cloud by the CPR cloud mask ( $> 30$ ). Note, cross-sections from the Envisat and CloudSat overpasses did not collocate in space and time.
